- Accurate core body temperature measurement must be obtained using a low-reading core temperature probe that measures as low as 25°C.
- Core body temperature must be > 32°C before terminating resuscitation efforts.
- Extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass may be considered in hypothermic patients with hemodynamic instability or cardiac arrest.

General Considerations

Systemic hypothermia is defined as core body temperature below 35°C. This may be primary, from exposure to prolonged ambient, extremely low temperature, or secondary, due to thermoregulatory dysfunction. Both may be present at the same time.

Hypothermia must be considered in any patient with prolonged exposure to an ambient cold environment, especially in patients with prior cold weather injury as well as the risk factors listed in the Cold & Heat section. In prolonged or repetitive cold exposure, hypothermia ensues if the body’s thermoregulatory responses become impaired.

Clinical Findings

Symptoms and signs of hypothermia are typically nonspecific and markedly variable based on the patient's underlying health and circumstances of cold exposure. All patients must be evaluated for associated conditions including hypoglycemia, trauma, infection, overdose, and peripheral cold injury. Laboratory studies should assess acid-base status; electrolytes, particularly potassium and glucose; kidney, liver, and pancreas function; coagulation; and rhabdomyolysis. Inaccurate laboratory values will occur if the blood sample is warmed to 37°C for testing.

Accurate core body temperature measurements must be obtained using a core temperature probe that measures as low as 25°C. **Stage I hypothermia** is seen when the core body temperature is between 32°C and 35°C and is defined by shivering and possibly poor judgment or coordination but with hemodynamic stability and a normal level of consciousness. **Stage II hypothermia** correlates with core body temperature 28–32°C. *Shivering stops*; bradycardia, dilated pupils, slowed reflexes, cold diuresis, and confusion and lethargy ensue. The ECG may reveal a J wave or Osborn wave (positive deflection in the terminal portion of the QRS complex, most notable in leads II, V_5, and V_6) (Figure 42–1). When the core body temperature is below 28°C, the likelihood of hemodynamic instability and cardiac arrest increases dramatically. **Stage III hypothermia** (core body temperature 24–28°C) is characterized by loss of consciousness but present vital signs. **Stage IV hypothermia** (core body temperature < 24°C) is the loss of vital signs. Coma, loss of reflexes, asystole, or ventricular fibrillation may falsely lead the clinician to assume the patient is dead despite reversible hypothermia.

Treatment

Rewarming is the initial, imperative treatment for all hypothermic patients. Resuscitation begins with rapid assessment and support of airway, breathing, and circulation, simultaneously with the initiation of rewarming, and prevention of further heat loss. All cold, wet clothing must be removed and replaced with warm, dry clothing and blankets.

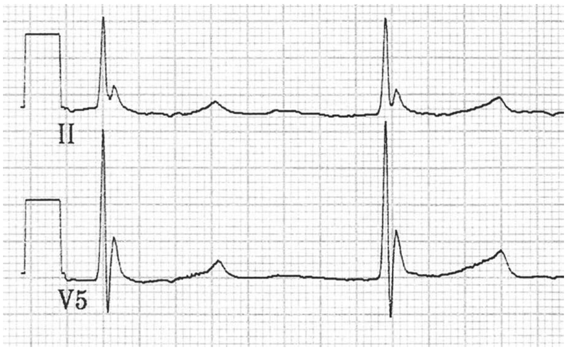

Figure 42–1. ECG shows leads II and V_5 in a patient whose body temperature is 24°C. Note the bradycardia and Osborn waves. These findings become more prominent as the body temperature lowers and gradually resolve with rewarming. Osborn waves have an extra positive deflection in the terminal portion of the QRS complex and are best seen in the inferior and lateral precordial leads (most notably in leads II, V_5, and V_6).

Mild or stage I hypothermia can be treated with *passive external rewarming* (eg, removing and replacing wet clothes with dry ones) or by active external rewarming. In contrast to those with more severe hypothermia, it is safe and recommended for the uninjured patient with mild hypothermia to become physically active to generate heat. *Active external rewarming* is noninvasive, highly effective, and safe for mild hypothermia. It involves applying external heat to the patient's skin. Examples include warm bedding, heated blankets, heat packs, and immersion into a 40°C bath. Patients with mild hypothermia and previous good health usually respond well to passive and active external warming.

Stage II and III hypothermia are treated as above with the addition of more aggressive rewarming strategies. This requires close monitoring of vital signs and cardiac rhythm during rewarming. Warm intravenous fluids (38–42°C) are considered minimally invasive and effective.

As hypothermia becomes more severe, there are increased complications of both hypothermia itself and of rewarming. Complications of rewarming occur as colder peripheral blood returns to central circulation. This may result in *core temperature afterdrop*, rewarming lactic acidosis from shunting lactate into the circulation, rewarming shock from peripheral vasodilation and hypovolemia, ventricular fibrillation, and other cardiac arrhythmias. Afterdrop can be lessened by active external rewarming of the trunk but not the extremities and by avoiding any muscle movement by the patient. Extreme caution must be taken when handling the hypothermic patient to avoid triggering potentially fatal arrhythmias in a phenomenon known as rescue collapse.

Patients with hemodynamic instability or cardiac arrest should be transferred to a facility with ECMO or cardiopulmonary bypass capability.

Early recognition and advanced management guidelines are needed for patients with stage IV hypothermia. *For hypothermic patients in cardiac arrest, high-quality CPR must be initiated and continued until the patient's core body temperature is at least 32°C.* Below 30°C, arrhythmias and asystole may be refractory to drug therapy until the patient has been rewarmed; therefore, treatment should focus on excellent CPR technique in conjunction with aggressive rewarming of the patient. Epinephrine may be given in cardiac arrest of the severely hypothermic patient. The International Commission for Mountain Emergency Medicine recommends extracorporeal life support as the treatment of choice for patients at high risk for hypothermic cardiac arrest. Extracorporeal life support has been shown to substantially improve survival of patients with unstable circulation or cardiac arrest.

Hypothermic patients with return of spontaneous circulation are at high risk of subsequent multiorgan system failure.

When to Admit

Hypothermia patients must undergo close monitoring for potential complications. This is typically done during an inpatient admission or prolonged emergency department observation.

HYPOTHERMIA OF THE EXTREMITIES

ESSENTIALS OF DIAGNOSIS

- *"Keep warm, keep dry, and keep moving"* to prevent cold-induced injury.
- Rewarming of the extremity suffering cold-induced injury must be performed as soon as possible once there is no risk of refreezing; exercise, rubbing, or massage must be avoided during rewarming.

Clinical Findings

Cold exposure of the extremities produces immediate localized and then generalized vasoconstriction, which may result in a wide range of injuries. Tissue damage occurs because of ischemia and intravascular thromboses, endothelial damage, or actual freezing. Freezing (frostbite) may occur when skin temperatures drop or in the presence of wind, water, immobility, malnutrition, or vascular disease.

For all forms of cold-induced injury to an extremity, caution must be taken to avoid rubbing or massaging the injured area and to avoid applying moisture, ice, or heat. The cold-injured extremity must be protected from trauma, secondary infection, and further cold exposure.

Prevention

"Keep warm, keep dry, and keep moving." For optimal prevention of frostbite, individuals must wear warm, dry clothing. Arms, legs, fingers, and toes must be exercised to maintain circulation. Wet clothing, socks, and shoes must be replaced with dry ones. Risk factors include underlying diseases or medications that decrease tissue perfusion and prolonged cold environmental exposure. Caution must be taken to avoid cramped positions; wet or constrictive clothing; prolonged dependency of the feet; use of tobacco, alcohol, and sedative medications; and exposure to wet, muddy ground and windy conditions.

FROSTNIP & CHILBLAINS (Erythema Pernio)

Frostnip is a superficial nonfreezing injury causing local paresthesias of the involved area that completely resolves with passive external rewarming.

Chilblains, or **erythema pernio,** are inflammatory skin changes caused by exposure to cold without actual freezing of the tissues. These skin lesions may be red or purple papular lesions, which are painful or pruritic, with burning or paresthesias. They may be associated with edema or blistering and aggravated by warmth. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Treatment consists of elevating and passively externally rewarming the affected part.

IMMERSION FOOT OR TRENCH FOOT

Immersion foot ("trench foot") or **hand** is caused by prolonged immersion in cold water or mud, usually below 10°C. **Prehyperemic stage** is marked by early symptoms of cold and anesthesia of the affected area. **Hyperemic stage** follows with a hot sensation, intense burning, and shooting pains. **Posthyperemic stage** occurs with ongoing cold exposure; the affected part becomes pale or cyanotic with diminished pulsations due to vasospasm. This may result in blistering, swelling, redness, ecchymoses, hemorrhage, necrosis, peripheral nerve injury, or gangrene.

Treatment consists of air drying and gradual rewarming by exposure to air at room temperature. Affected parts are elevated to aid in removal of edema fluid. Pressure sites are protected with cushions. Bed rest is required until all ulcers have healed.

FROSTBITE

Frostbite is injury from tissue freezing and formation of ice crystals in the tissue. Most tissue destruction follows reperfusion of the frozen tissues resulting in further tissue damage. In mild cases, only the skin and subcutaneous tissues are involved. Symptoms include numbness, prickling, itching, and pallor. With increasing severity, deeper structures become involved; the skin appears white or yellow, loses elasticity, and becomes immobile. Edema, hemorrhagic blisters, necrosis, gangrene, paresthesias, and stiffness may occur.

Treatment

A. Immediate Treatment

Evaluate and treat the patient for associated systemic hypothermia, concurrent conditions, and injury. Early use of systemic analgesics is recommended for nonfrozen injuries. Hydrate the patient to avoid hypovolemia and to improve perfusion.

1. Rewarming—Rapid rewarming at temperatures slightly above normal body temperature may significantly decrease tissue necrosis and reverse the tissue crystallization. *If there is any possibility of refreezing, the frostbitten part must not be thawed.* Ideally, the frozen extremity should not be used, but if required for evacuation, the affected frozen extremity must be padded and splinted to avoid additional injury. *Rewarming is best accomplished by warm bath immersion.* The frozen extremity is immersed in a moving water bath heated to 37–39°C for approximately 30 minutes until the area becomes soft and pliable to the touch. Water in this temperature range feels warm but not hot to the normal hand or wrist. If warm water is not available, then passive thawing in a warm environment must be allowed. Dry heat is not recommended because it is more difficult to regulate and increases the likelihood of accidental burns. Thawing may cause tenderness and burning pain. Once the frozen part has thawed and returned to normal temperature, discontinue external heat. *In the early stage, rewarming by exercise, rubbing, or friction is contraindicated.* The patient must be kept on bed rest with the affected parts elevated and uncovered at room temperature. Avoid application of casts, occlusive dressings, or bandages. Blisters should be left intact unless signs of infection develop.

2. Anti-infective measures and wound care—Frostbite increases susceptibility to tetanus and infection. Tetanus prophylaxis status should be verified and updated as needed. Infection risk may be reduced by aseptic wound care. Topical wound care such as aloe vera cream or gel or antibiotic ointment should be applied to the thawed tissue before application of dressings. Nonadherent sterile gauze and fluffy dressing must be loosely applied to wounds and cushions used for all areas of pressure. Systemic antibiotics should not be administered empirically.

B. Medical and Surgical Treatment Options

Telemedicine may be used so that specialists can provide advice on early field treatment of patients in remote areas, thereby improving outcomes. NSAIDs should be administered (in the absence of contraindications) until frostbite wounds are healed or surgical management occurs. Clinicians must watch for evidence of compartment syndrome and need for fasciotomy. Eschar formation without evidence of infection may be conservatively treated. The underlying skin may heal spontaneously with the eschar acting as a biologic dressing. Rates of amputation have been reduced with intravenous infusions of synthetic prostaglandins and tissue plasminogen activators, and with intra-arterial administration of a thrombolytic within 24 hours of exposure. The rate of tissue salvage decreases with every hour of delay from rewarming to thrombolytic therapy.

C. Follow-Up Care

Patient education must include ongoing care of the cold injury and prevention of future hypothermia and cold injury. Gentle, progressive physical therapy to promote circulation should be instituted as tolerated.

Prognosis

Recovery from frostbite depends on the underlying comorbidities, the extent of initial tissue damage, the rewarming reperfusion injury, and the late sequelae. The involved extremity may be at increased susceptibility for discomfort and injury upon re-exposure to cold. Neuropathic sequelae include pain, numbness, tingling, hyperhidrosis, and cold sensitivity of the extremities. Nerve conduction abnormalities may persist for many years after a cold injury.

When to Admit

- Management of tissue damage, comorbidities, associated injuries.
- Need for hospital-based interventions.
- Psychosocial factors that could compromise patient safety or recovery.

DROWNING

ESSENTIALS OF DIAGNOSIS

- The first requirement of rescue is immediate rescue breathing and CPR.
- Clinical manifestations include hypoxemia, pulmonary edema, and hypoventilation.
- Patients must be assessed for hypothermia, hypoglycemia, concurrent injuries, and medical conditions.

General Considerations

According to the WHO, drowning is the third leading cause of unintentional injury death worldwide. Drowning, as defined by the WHO, is any "process of experiencing respiratory impairment from submersion/immersion in liquid." Drowning may result in asphyxiation (from fluid aspiration or laryngospasm), hypoxemia, hypothermia, and acidemia. Outcomes from drowning range from life without morbidity to death. Morbidity may be immediate or delayed. A patient may be deceptively asymptomatic during the initial recovery period only to deteriorate or die from acute respiratory failure within the following 12–24 hours. Disseminated intravascular coagulation may also lead to bleeding after asphyxiation from drowning.

Drowning is a leading cause of death in children worldwide and is highly preventable in all ages with implementation of educational and safety measures. Clinicians must provide patient education and guidance about drowning prevention.

Clinical Findings

A. Symptoms and Signs

The patient's appearance may vary from asymptomatic to marked distress with abnormal vital signs. Symptoms and signs include respiratory difficulty, trismus, chest pain, dysrhythmia, hypotension, cyanosis, and hypothermia (from cold water or prolonged submersion). A pink froth from the mouth and nose indicates pulmonary edema. The patient may experience headache, neurologic deficits, and altered level of consciousness.

B. Laboratory Findings

Metabolic acidosis is common and ABG results may be helpful in determining the degree of injury since initial clinical findings may appear benign. PaO_2 is usually decreased; $PaCO_2$ may be increased or decreased; pH is decreased. Bedside blood glucose must be checked rapidly. Other testing is based on clinical scenario.

Prevention

Education and prevention are critical given the high burden of disease from drowning.

Preventive measures must be taken to reduce morbidity and mortality from drowning. Conditions that increase risk of submersion injury include the use of alcohol, psychotropics, and other drugs, inadequate water safety skills, poor physical health, hyperventilation, sudden acute illness, acute trauma, decompression sickness, dangerous water conditions, and environmental hazards (eg, lack of fencing around pools).

Treatment

A. First Aid

1. The first requirement of rescue is immediate basic life support treatment and CPR. At the scene, immediate airway management and measures to combat hypoxemia are critical to improve outcome.
2. Patient must be assessed for hypothermia, hypoglycemia, concurrent medical conditions, and associated trauma.
3. Rescuer must not attempt to drain water from the person's lungs.
4. Resuscitation and basic life support efforts must be continued until core body temperature reaches 32°C.

B. Subsequent Management

1. Ensure optimal ventilation and oxygenation—The onset of hypoxemia exists even in the alert, conscious patient who appears to be breathing normally. Supplemental oxygen should be administered immediately at the highest available concentration to maintain oxygen saturation at 90% or higher.

Serial physical examinations and CXRs must be performed to detect possible pneumonitis, atelectasis, and pulmonary edema. Bronchodilators may be used to treat wheezing. Nasogastric suctioning may be necessary to decompress the stomach.

2. Cardiovascular support—Intravascular volume status must be monitored and supported by vascular fluid replacement, vasopressors, or diuretics as needed.

3. Correction of blood pH and electrolyte abnormalities—Metabolic acidosis is present in most persons who drown but typically corrects through adequate ventilation and oxygenation. Glycemic control improves outcome.

4. Cerebral and spinal cord injury—CNS damage may progress despite apparently adequate treatment of hypoxia and shock.

5. Hypothermia—Core body temperature must be measured and managed as appropriate (see Accidental Systemic Hypothermia, above).

Course & Prognosis

Favorable prognosis is related to a duration of submersion < 5 minutes, with worsening outcomes correlating with increased submersion times. Respiratory damage is often severe in the minutes to hours following a drowning. With appropriate respiratory supportive treatment, patients may improve rapidly over the first few days following the drowning. Long-term complications of drowning may include neurologic impairment, seizure disorder, and pulmonary or cardiac damage. Prognosis is directly correlated with the patient's age, submersion time, rapidity of prehospital resuscitation and subsequent transport to a medical facility, clinical status at time of arrival to hospital, Glasgow Coma Scale score, pupillary reactivity, and overall health assessment (APACHE II score).

When to Admit

Most patients with significant drowning or concurrent medical or traumatic conditions require inpatient monitoring following the event. This includes continuous monitoring of cardiorespiratory, neurologic, renal, and metabolic function. Pulmonary edema may not appear for 24 hours.

THERMAL BURNS

ESSENTIALS OF DIAGNOSIS

- Estimates of the burn location, size, and depth greatly determine the treatment plan.
- The first 48 hours of burn care offer the greatest impact on morbidity and mortality of a patient with burns.

Worldwide, burns are a common cause of injury and potential morbidity and mortality. Burn prognosis is affected by the type of environment where the burn occurred. Low-resource settings (wilderness or low-income areas) are associated with delays in and suboptimal access to standard burn treatments.

The first 48 hours after thermal burn injury offer the greatest opportunity to impact the survival of the patient. Early surgical intervention, wound care, enteral feeding, glucose control and metabolic management, infection control, and prevention of hypothermia and compartment syndrome have contributed to significantly lower mortality rates and shorter hospitalizations.

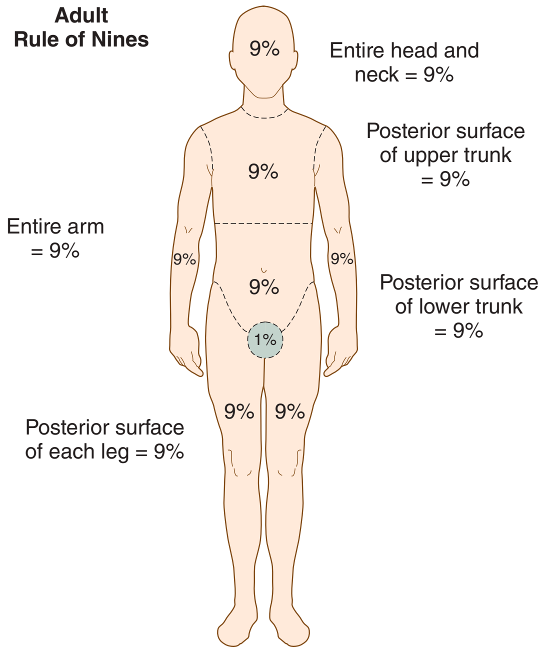
General Considerations

A. Classification

Burns are classified by extent, depth, patient age, and associated illness or injury. Accurate estimation of burn size and depth is necessary to quantify the parameters of resuscitation.

1. Extent—In adults, the "*rule of nines*" (Figure 42–2) is useful for rapidly assessing the extent of a burn. It is important to expose the entire patient to make an accurate assessment of skin findings on initial and subsequent examinations. One rule of thumb is that the palm of an open hand in adult patients constitutes 1% of *total body surface area (TBSA)*. TBSA is calculated for partial- and full-thickness burns.

2. Depth—Judgment of depth of injury is difficult. *Superficial burns* may appear red or gray but will demonstrate excellent capillary refill and are not blistered initially. If the wound is blistered and appears pink and wet, this represents a *superficial partial-thickness burn*. *Deep partial-thickness burns* appear white and wet, and bleed if poked; cutaneous sensation is maintained. *Full-thickness burns* result in a loss of adnexal structures and may appear white-yellow or may have a black charred appearance. This stiff, dry skin does not bleed when poked and cutaneous sensation is lost.



Adult
Rule of Nines
9%
Entire head and neck = 9%
9%
Posterior surface of upper trunk = 9%
Entire arm = 9%
9%
9%
9%
Posterior surface of lower trunk = 9%
1%
9%
9%
Posterior surface of each leg = 9%

Figure 42–2. Estimation of body surface area in burns.

Deep partial-thickness and full-thickness burns are treated in a similar fashion. Both require early debridement and grafting to heal appropriately, without which the skin becomes thin and scarred.

B. Survival After Burn Injury

Transfer to a burn unit is determined by large burn size, circumferential burn, or burn involving a joint or high-risk body part, and by comorbidities. Mortality rates have been significantly reduced due to treatment advances including improvements in wound care, treatment of infection, early burn excision, skin substitute usage, and early nutritional support.

C. Associated Injuries or Illnesses

Smoke inhalation, associated trauma, and electrical injuries are commonly associated with burns. Severe burns from any source may result in similar complications (eg, infections, respiratory compromise, multiorgan dysfunction, VTE, and GI complications).

D. Systemic Reactions to Burn Injury

Burns > approximately 20% of TBSA may lead to systemic metabolic derangements requiring intensive support. The inflammatory cascade can result in shock and coagulopathy.

Treatment

A. Initial Resuscitation

1. Primary survey—Patients with severe burns require a full trauma assessment, starting with "ABCDE" (airway, breathing, circulation, disability, exposure).

A. AIRWAY CONTROL—Serial assessments of airway and breathing are necessary because airway compromise and ARDS may develop, particularly in those with inhalation injury.

B. VASCULAR ACCESS—Vascular access must be obtained on all patients with severe burns.

C. FLUID RESUSCITATION—Patients with burns > 15% of TBSA require intravascular fluid administration of large volumes of crystalloid. The most widely recognized guideline for fluid resuscitation is the *Parkland formula* (https://www.mdcalc.com/parkland-formula-burns) in which the fluid requirement in the first 24 hours is estimated as 4 mL/kg × body weight per percentage of body surface area burned. Half the calculated fluid is given in the first 8-hour period from the time of injury. The remaining fluid is delivered over the next 16 hours. An extremely large volume of fluid may be required. Crystalloid solutions alone may be insufficient to restore cardiac preload during the period of burn shock and colloid adjuncts may be considered to optimize fluid resuscitation. Clinicians must monitor for clinical signs of volume overload as it may lead to pulmonary complications or compartment syndromes. Electrical burns and inhalation injury may increase the fluid requirement.

B. Management

1. Pain control—Pain control is critical in patients with burn injuries. Treatment is with (oral or intravenous) NSAIDs and opioids (see Chapter 5).

2. Chemoprophylaxis—

A. Tetanus immunization—Verify and update tetanus prophylaxis status *in all patients with burns*. (See Chapter 38.)

B. Antibiotics—All nonsuperficial wounds need to be covered with topical antibiotics. Prophylaxis with systemic antibiotics is not indicated.

3. Surgical management—

A. Escharotomy—As tissue swelling occurs, ischemia may develop under any constricting eschar of an extremity, neck, or chest, or in circumferential full-thickness burns of the trunk. Escharotomy incisions can be limb- and life-saving.

B. Fasciotomy—Fasciotomy is indicated for any compartment syndrome. Clinicians must frequently monitor patients for development of early signs of a compartment syndrome, particularly in those with circumferential burns.

C. Debridement, dressings, and topical and systemic antibiotic therapy—Minor burn wounds must be debrided to determine the depth of the burn and then thoroughly cleansed. Thereafter, *daily wound care must consist of debridement as needed, topical antibiotics, and wound dressings*. Patient compliance and adequate pain control is essential for successful outpatient treatment. The wound must be reevaluated by the treating clinician within 24–72 hours to evaluate for signs of infection.

The goal of burn wound management is to protect the wound from desiccation and avoid further injury or infection. Regular and thorough cleansing of burned areas is critical. Topical antibiotics may be applied after wound cleansing. Silver sulfadiazine is *no longer recommended*.

It is imperative to closely monitor for and treat systemic infection, since this remains a leading cause of morbidity among patients with major burn injuries. Health care–associated infections are increasingly common.

D. Wound management—*The goal of therapy after fluid resuscitation is rapid and stable closure of the wound*. Wounds that do not heal spontaneously in 7–10 days (eg, deep partial-thickness or full-thickness burns) are best treated by a specialist through excision and autograft to avoid development of granulation and infection. The quality of the skin in regenerated deep partial-thickness burns is marginal because of the very thin dermis that emerges.

Cultured allogeneic keratinocyte grafts can provide rapid early coverage for superficial burn injuries. Skin substitution with cultured grafts may be life-saving for severe burns. Although the replaced dermis has nearly normal histologic dermal elements, there are no adnexal structures present, and very few, if any, elastic fibers.

E. Abdominal compartment syndrome—Abdominal compartment syndrome is a potentially lethal condition that may develop in severely burned patients, with mortality rates of approximately 60% despite surgical intervention. Diagnosis is confirmed by bladder pressures > 30 mm Hg in at-risk patients. Surgical abdominal decompression may improve ventilation and oxygen delivery but may not impact survival.

C. Patient Support

Patients with severe burns require extensive supportive care, both physiologically and psychologically. It is important to maintain normal core body temperature and avoid hypothermia, by maintaining environmental temperature at or above 30°C, in patients with burns over more than 20% of TBSA. These patients are at risk for many complications such as respiratory injury, ARDS or respiratory failure unresponsive to maximal ventilatory support, sepsis, multiorgan failure, and VTE.

Patients with severe burns have increased metabolic and energy needs for wound healing and require careful assessment and provision of optimal nutrition. Early aggressive nutrition (by parenteral or enteral routes) reduces infections, recovery time, noninfectious complications, length of hospital stay, long-term sequelae, and mortality.

Prevention of long-term scars remains a formidable problem in seriously burned patients.

Prognosis

Prognosis depends on the extent and location of the burn tissue damage, associated injuries, comorbidities, and complications. Hyperglycemia is a predictor of worse outcomes. Common complications include sepsis; gangrene requiring limb amputation; or neurologic, cardiac, cognitive, or psychiatric dysfunction. Psychiatric support may be necessary following burn injury.

When to Refer

Transfer to a **burn unit** is indicated for large burn size (for partial-thickness burns > 10% of TBSA or for full-thickness burns > 5% of TBSA), circumferential burn, inhalation injury, or burn involving a joint or high-risk body part (face, hands, feet, genitalia), and for patients with comorbidities.

When to Admit

- All patients with severe burns require extensive supportive care, both physiologically and psychologically.
- Significant burns (based on location and extent).
- Patients with significant comorbidities and suboptimal home situations.
- *Burn center consultation* can advise which patients require transfer and which can be managed via telemedicine/telephone consultation.

- Monitoring includes vital signs, wound care, and observation for potential complications of electrolyte abnormalities, AKI, hepatic failure, cardiopulmonary compromise, hyperglycemia, and infection.

ELECTRICAL INJURY

ESSENTIALS OF DIAGNOSIS

- After an electrical injury, clinical findings suggestive of death are unreliable; resuscitation must begin immediately.
- Extent of damage from electrical injury is determined by the type, amount, duration, and pathway of current.
- Electrical injury skin findings are not indicative of the depth of tissue injury and may appear misleadingly minor.

General Considerations

Electricity injuries occur by exposure to electrical current of low voltage, high voltage, or lightning. Electrical current type is either alternating current or direct current and is measured in volts (V). Electrical injury is caused by a combination of direct thermal injury and tissue damage, muscle tetany, coagulation necrosis, associated trauma, and delayed sequelae. Treatment is different than for other types of burns. Electricity-induced injuries are common and yet most are preventable.

Alternating current is an electric current that may cause muscle tetany, which prolongs the duration and amount of exposure. Alternating current can be low voltage or high voltage. Most households and businesses use electric power of alternating current at low voltages (< 1000 V). Low-voltage electrical injuries range from minor to significant damage and death. High-voltage (> 1000 V) alternating current electrical injuries are often related to occupational exposure and associated with deep tissue damage, and higher morbidity and mortality. *Direct current* is unidirectional electrical flow (eg, lightning, batteries). It is more likely to cause a single intense muscle contraction and asystole. Lightning differs from other high-voltage electrical shock because lightning delivers a direct current of millions of volts in a fraction of a second.

The extent of damage from electrical injury is determined by the current type, amount (voltage), duration of exposure, pathway of current, tissue resistance, moisture, associated trauma, and comorbidities. Current is the most important determinant of tissue damage and causes direct thermal injury. Tissue resistance varies throughout the body with nerve cells being the most vulnerable and bone the most resistant to electrical current.

Clinical Findings

Electrical burns are of three types: *flash (arcing) burns, flame (clothing) burns,* and the *direct heating effect* of tissues by the current.

Skin damage does not correlate with the degree of injury. Symptoms and signs may range from very subtle to death. The presence of entrance and exit burns signifies an increased risk of deep tissue damage and compartment syndrome. Current passing through skeletal muscle can cause muscle necrosis and contractions severe enough to result in bone fracture.

Resuscitation must be initiated on all victims of electrical injury since clinical findings of death are deceptive and unreliable.

Complications

Complications may include cardiac or respiratory arrest; dysrhythmias; neurologic dysfunction; paralysis; headache; neuropathy; vascular injury from thrombosis and capillary damage; tissue edema and necrosis; compartment syndrome; associated traumatic injuries; pneumothorax; rhabdomyolysis; AKI; hypovolemia from third spacing; infections; otic damage; ocular complications; sepsis; gangrene requiring limb amputation; and cognitive or psychiatric dysfunction. Psychiatric support may be necessary following electrical injury.

Treatment

A. Emergency Measures

The patient must be safely separated from the electrical current prior to CPR initiation and treatment. Resuscitation must be initiated since clinical findings suggesting death are unreliable. The patient must be assessed and treated for acute medical conditions and trauma.

B. Hospital Measures

Electric burn assessment follows the full trauma protocol starting with airway, breathing, circulation, and disability. Fluid resuscitation is important. Initial evaluation includes ECG, cardiac monitoring, cardiac enzymes, CBC, electrolytes, kidney tests, liver chemistries, creatine phosphokinase or urine myoglobin, and UA. Patients must be evaluated for injuries including burns, blunt trauma, dehydration, hypertension, acid-base disturbances, and neurologic and psychological trauma.

Electrical burn wounds can be devastating with wide-ranging and significant complications. Superficial skin may appear deceivingly benign. *There must be a high suspicion for extensive deep tissue necrosis, which leads to profound tissue swelling and high risk of compartment syndrome.*

Pain management is important throughout initial treatment and subsequent rehabilitation.

Prognosis

Prognosis is determined by the degree and location of electrical injury, initial tissue damage, associated injuries, comorbidities, and complications.

When to Refer

- An ophthalmologist may evaluate for possible ocular complications; an otologist may evaluate for ear trauma or hearing loss.
- Surgical specialists may need to perform fasciotomy for compartment syndrome, debridement of devitalized tissue, or microvascular reconstruction.
- A psychiatrist may assess any psychological impact.

When to Admit

Indications for hospitalization include high-voltage exposure; abnormal cardiac rhythm or ECG changes; large burn size; neurologic, pulmonary, or cardiac symptoms; suspicion of significant deep tissue or organ damage; transthoracic current pathway; history of cardiac disease or other significant comorbidities or injuries; and need for surgery.

RADIATION EXPOSURE

ESSENTIALS OF DIAGNOSIS

- Damage from radiation is determined by the radiation type, quantity, duration, accumulated exposures, and the patient's underlying conditions.
- Clinicians and patients must be educated regarding the risks of medical diagnostic radiation weighed against the benefits of the medical imaging needed.

General Considerations

Radiation exposure may occur from environmental, occupational, medical care, accidental, or intentional causes. The extent of damage from radiation exposure depends on the type, quantity, and duration of radiation exposure; the organs exposed; and the patient's age, comorbidities, and accumulated radiation exposures.

Radiation occurs from both nonionizing and ionizing radiation sources. *Nonionizing radiation* is low energy, causing local thermal damage. *Ionizing radiation* is high energy, causing damage in several ways. Exposure may be external, internal, or both. Radiation causes multiple metabolic changes resulting in tissue-specific damage.

The *International Commission on Radiological Protection (ICRP)* website provides the most current recommendations for protection against ionizing radiation (http://www.icrp.org/index.asp). The WHO publishes guidelines on radiation emergencies (https://www.who.int/health-topics/radiation-emergencies#tab=tab_1). These guidelines include recommended interventions during the early, intermediate, and late emergency phases and the management of their psychosocial impact.

Clinical Findings

Radiation exposure results in acute and delayed effects. It is important to obtain the event history, radiation exposure, and coexisting injuries or conditions. Acute effects over hours to days after exposure involve damage to rapidly dividing cells (eg, the mucosa, skin, and bone marrow). *Acute findings* include mucositis, nausea, vomiting, GI edema and ulcers, skin burns, and bone marrow suppression. *Delayed effects* include malignancy, reproduction abnormalities, and liver, kidney, CNS, and immune system dysfunction.

Acute radiation syndrome is a clinical syndrome due to an exposure to high dose(s) of ionizing radiation over a brief time course. Acute radiation syndrome involves multiple organ systems, including hematopoietic, cardiopulmonary, GI, neurovascular, and cutaneous systems. The symptom onset is within hours to days depending on the dose. Symptoms include anorexia, nausea, vomiting, weakness, exhaustion, dehydration, lassitude, prostration, anemia, and infection; these symptoms may occur singly or in combination. The CDC offers information regarding acute radiation syndrome (https://www.cdc.gov/radiation-emergencies/hcp/clinical-guidance/ars.html?CDC_AAref_Val=https://www.cdc.gov/nceh/radiation/emergencies/arsphysicianfactsheet.htm).

Treatment for acute radiation exposure includes close monitoring of the GI, cutaneous, hematologic, cardiopulmonary, and neurovascular systems from initial exposure and over time.

Therapeutic Radiation Exposure

Radiation therapy has been a successful component in the treatment of many malignancies. Unfortunately, these radiation-treated cancer survivors have a higher risk of a second malignancy; obesity; and pulmonary, cardiac, and thyroid dysfunction, as well as an increased overall risk of chronic health conditions and mortality.

Medical Imaging Radiation Exposure

Medical imaging with ionizing radiation exposure has dramatically increased over the past few decades. With the rising use of medical imaging, there is international focus on improving the safety by standardization and regulation of radiation dosing in medical diagnostics and education for clinician and the public.

The American College of Radiology (ACR) provides "*ACR Appropriateness Criteria*," which are evidence-based guidelines created by expert panels to serve as a reference for best practices for imaging decisions by health care providers (https://www.acr.org/Clinical-Resources/ACR-Appropriateness-Criteria). Clinicians and patients must carefully weigh the risks and benefits of radiation exposure when deciding on an imaging test.

Occupational & Environmental Radiation Exposure

Useful resources for professionals include the *CDC "Radiation Emergencies" website* (https://www.cdc.gov/nceh/radiation/emergencies/index.htm) and the *National Nuclear Security Administration's Radiation Emergency Assistance Center*, which provides 24-hour access to expert consultation services (telephone: 1-865-576-1005 or website: https://orise.orau.gov/reacts/index.html).

Treatment

Treatment is focused on decontamination, on management of coexisting conditions or injuries, and on supportive care. Specific supportive treatments are determined by the dose, route, and effects of exposure and associated conditions present.

Prognosis

Prognosis is determined by the radiation dose, duration, and frequency as well as by the underlying condition of the patient. Death following acute radiation exposure is usually due to hematopoietic failure, mucosal damage, CNS damage, widespread vascular injury, or secondary infection.

Carcinogenesis is related to the radiation type, total dose, duration, and accumulated exposure, and to the susceptibility of the patient. Radiation-related cancer risks persist throughout the exposed person's life span.

With the increased use of ionizing radiation for medical diagnostics and treatments, there is an iatrogenic increase in radiation-induced cancer risks. There are age-related sensitivities to radiation; pregnant women and younger persons are more susceptible to carcinogenesis.

When to Admit

Most patients with significant ionizing radiation exposure require admission for close monitoring and supportive treatment.

ENVIRONMENTAL DISORDERS RELATED TO ALTITUDE

DYSBARISM & DECOMPRESSION SICKNESS

ESSENTIALS OF DIAGNOSIS

- Early recognition of symptoms temporally related to recent large changes in altitude or pressure and prompt treatment of decompression illness are extremely important for optimal outcome.
- Patients with decompression illness must also be assessed for hypothermia, trauma, hypoglycemia, and other medical conditions.
- Decompression illness must be considered if symptoms are temporally related to recent diving or rapid changes in altitude or pressure within 48 hours after surfacing.
- Consultation with diving medicine or hyperbaric oxygen specialist is indicated.

General Considerations

Dysbarism and decompression illness may result from altitude changes and effects of environmental pressure on the gases in the body. These are more likely to occur when scuba diving is followed closely by rapid ascent, or when the scuba diver is not adherent to the conservative dive guidelines for dive duration, course, depth, and surface times between dives.

As a diver descends, the gases in the body compress and dissolve throughout areas of the body that are both compressible (lungs, GI tract) and noncompressible (sinuses, joints). As the diver descends further, the increased pressure on the body's gases increases the amounts of gases dissolved into the bloodstream and tissues. During the dive ascent, these dissolved gases expand within the body, which can cause dysbarism and decompression illness.

Dysbarism results from barotrauma when gas compression or expansion occurs in parts of the body that are noncompressible or have limited compliance. **Pulmonary overinflation syndrome** is one of the most serious and potentially fatal results of barotrauma. This syndrome is due to an inappropriately rapid ascent causing alveoli rupture and air bubble extravasation into the vital organs or the cerebral circulation.

Decompression illness occurs when the pressure change from higher pressure to lower pressure is too rapid causing gas bubbles to form and cause damage to their location (eg, coronary, pulmonary, spinal, or cerebral blood vessels, joints, soft tissues). Decompression illness symptoms depend on the released gas bubbles' size, number, and location. Scuba diving risk of decompression illness depends on multiple factors: the dive details (depth, duration, number of dives, interval surface time between dives, and water conditions). Patient factors include age, weight, overall health, physical condition, physical exertion, the rate of ascent, and the length of time between the low altitude and high altitude. Predisposing factors include obesity, injury, hypoxia, lung, or cardiac disease, right to left cardiac shunt, dehydration, alcohol and medication effects, and stress response. Decompression illness may also occur in those who take hot showers after cold dives.

Preventive measures include pre-dive medical screening and dive planning; diver education and training; strict adherence to dive course, timing, and depths; and a slow and controlled ascent with proper control of buoyancy. Conservative recommendation is to *avoid high altitudes (ground ascent or air travel) for at least 24 hours after surfacing* from the dive, especially following multiple dives.

Clinical Findings

Clinical manifestations depend on the location of the gas bubble formation or the compressibility of gases in the body. Symptom onset may be immediate or within minutes or hours (up to 48 hours later). Decompression illness symptoms are wide-ranging: pain in the joints; skin pruritus or burning; cardiac; neurologic (symptoms may or may not follow typical neuroanatomic distribution patterns); respiratory compromise; pain in ears or sinuses, or both; coma; and death.

Decompression illness involving the brain and spinal cord may occur due to air bubbles causing arterial occlusion, venous obstruction, or in situ toxicity.

The initial assessment must include assessment of associated conditions of hypothermia, hypoglycemia, hypovolemia, aspiration, near-drowning, trauma, envenomation, and concurrent medical conditions.

Treatment

Early recognition and prompt treatment are extremely important including consultation with diving medicine or hyperbaric oxygen specialists. Decompression illness must be considered if symptoms are temporally related to recent diving or rapid changes in altitude or pressure within the past 48 hours. Continuous administration of 100% oxygen is indicated and beneficial for all patients. Hyperbaric oxygen treatment is commonly recommended for decompression illness symptoms. Immediate consultation with a diving medicine or hyperbaric oxygen specialist is indicated even if mild decompression illness symptoms resolve. NSAIDs, acetaminophen, or aspirin may be given for pain control if there are no contraindications. Opioids must be used very cautiously since these may obscure the response to recompression.

When to Admit

Rapid transportation to a hyperbaric treatment facility for recompression is imperative since this is the recommended treatment by specialists. The *Divers Alert Network* is an excellent worldwide resource for emergency advice 24 hours daily for the management of diving-related conditions (https://dan.org/).

HIGH-ALTITUDE ILLNESS

ESSENTIALS OF DIAGNOSIS

- The severity of high-altitude illness is affected by the rate and height of ascent and the individual's susceptibility.
- Prompt recognition and medical treatment of early findings of high-altitude illness may prevent progression.
- Clinicians must assess for conditions that may coexist or mimic symptoms of high-altitude illness.
- Immediate descent is the definitive treatment for high-altitude cerebral edema and high-altitude pulmonary edema.

General Considerations

As altitude increases, there is a decrease in both barometric pressure and oxygen partial pressure resulting in hypobaric hypoxia. High-altitude illnesses are due to hypobaric hypoxia at high altitudes (usually > 2000 meters or 6562 feet). High-altitude illness includes a spectrum of disorders categorized by end-organ effects (mostly cerebral and pulmonary) and exposure duration. Acute high-altitude illnesses are **acute hypoxia, acute mountain sickness (AMS), high-altitude cerebral edema (HACE),** and **high-altitude pulmonary edema (HAPE).**

Acclimatization occurs over time as a physiologic response to the increasing altitude and increasing hypobaric hypoxia. *High-altitude illness results when the hypoxic stress is greater than the individual's ability to acclimatize.* Risk factors for high-altitude illness include increased physical activity with insufficient acclimatization, inadequate education and preparation, individual susceptibility, and previous high-altitude illness. The key determinants of high-altitude illness risk and severity include both individual susceptibility factors and altitudinal factors, such as rate and height of ascent and total change in altitude over time.

Individual susceptibility factors include underlying conditions such as genetics, medications, social habits, and preexisting medical conditions. Those with symptomatic neurologic, cardiovascular, or pulmonary disease must avoid high altitudes.

Patient assessment for high-altitude illness must also include evaluation for other conditions, which may coexist or may present in a similar manner.

1. High-Altitude–Associated Neurologic Conditions: AMS & HACE

There is a spectrum of neurologic conditions caused by high altitude, ranging from AMS to HACE, the more serious form.

AMS includes symptoms such as headache (the most severe and persistent symptom), lassitude, drowsiness, dizziness, chilliness, nausea and vomiting, and difficulty sleeping. Later symptoms include irritability, difficulty concentrating, anorexia, insomnia, and increased headaches.

HACE includes the severe symptoms of AMS and results from cerebral vasogenic edema and cerebral cellular hypoxia. It usually occurs at elevations above 2500 meters (8202 feet) but may occur at lower elevations. Hallmarks are altered mental status, ataxia, severe lassitude, and encephalopathy. Examination findings may include confusion, ataxia, urinary retention or incontinence, focal neurologic deficits, papilledema, and seizures. Symptoms may progress to obtundation, coma, and death.

Treatment

Definitive treatment is immediate descent of at least 610 meters (2001 feet), and then continued descent until symptoms improve. Descent is essential if symptoms are persistent, severe, or worsening, or in the setting of HACE or HAPE. If immediate descent is not possible, portable hyperbaric chambers can provide symptomatic relief, but must not delay descent.

Initial treatment involves medications and oxygen administration to keep the pulse oximetry $S_pO_2 > 90\%$. Acetazolamide is an effective medication for both prophylaxis and treatment of mild symptoms of AMS. Dexamethasone is given for moderate to severe AMS. Dexamethasone is also the primary treatment for HACE. Acetazolamide can be added as an adjunct in severe HACE cases. Typically, symptoms resolve within 24–48 hours. HACE treatment must continue for at least 24 hours after resolution of symptoms or until descent is completed. Dexamethasone should not be given for longer than 7 days.

It is imperative for the clinician to assess for HAPE and other conditions which may mimic or coexist with AMS and HACE. If HAPE symptoms and signs are present along with HACE, nifedipine or a selective phosphodiesterase inhibitor may be added with caution for pulmonary vasodilation.

2. Acute HAPE

HAPE is the leading cause of death from high-altitude illness. The hallmark is markedly elevated pulmonary artery pressure followed by pulmonary edema. Early symptoms may appear within a few hours up to 36 hours after ascent to high-altitude. HAPE symptoms include incessant dry cough, headache, dyspnea disproportionate to exertion, decreased exercise performance, fatigue, dyspnea at rest, and chest tightness. Strenuous exertion must be avoided. As pulmonary edema progresses, wheezing, orthopnea, and hemoptysis may develop.

Physical findings may include tachycardia, mild fever, tachypnea, cyanosis, rales, wheezing, and rhonchi. The clinician must assess for other potential medical conditions that may mimic or coexist. Diagnosis is usually clinical; tests are nonspecific. Prompt recognition and medical attention to early symptoms of HAPE may prevent progression.

Treatment

Immediate descent (at least 610 meters [2000 feet]) is essential, although this may not be immediately possible and may not alone improve symptoms.

The patient must be placed at rest, reclined with head elevated, with oxygen administration to keep the pulse oximetry $S_pO_2 > 90\%$. Recompression in portable hyperbaric chambers will reduce symptoms but must not delay rapid or immediate descent.

If descent, oxygen, or portable hyperbaric chambers are not available or successful, nifedipine can be used as an adjunct. Selective phosphodiesterase inhibitors may provide effective symptom relief as an alternative or if nifedipine is not available, and these also may be used for HAPE prevention. Administering both nifedipine plus a phosphodiesterase inhibitor as pulmonary vasodilators is *not* recommended. Treatment for ARDS (see Chapter 9) is required for some patients. If neurologic symptoms are present concurrently with HAPE and do not resolve with improved oxygenation, dexamethasone may be added per HACE treatment guidelines.

There is an international effort to advance the understanding of HAPE through the research and database registry (https://www.altitude.org).

Prevention of High-Altitude Disorders

Pre-trip preventive measures include participant education, medical evaluation, pre-trip planning, optimal physical conditioning before travel, and adequate rest and sleep the day before travel and during the trip. Preventive efforts during ascent include reduced food intake, avoidance of alcohol and tobacco, and limiting any unnecessary physical activity during travel.

Gradual ascent is the most effective way to allow acclimatization. Low-risk ascension rate is 2 or more days to arrive at 2500–3000 meters. *The altitude reached during waking hours is not as important as the altitude at which the hiker sleeps.*

Medication prophylaxis may be prescribed for AMS and HACE if no contraindications exist. Prophylactic low-dose acetazolamide has been shown to reduce the incidence and severity of AMS and HACE when started 3 days prior to ascent and continued for 48–72 hours at high altitude. Dexamethasone is an alternative prophylactic medication for AMS and HACE.

Individuals with a history of HAPE should use medication prophylaxis to reduce the risk of recurrence. Nifedipine started the day before ascent and continued through the fourth day at target elevation, or through the seventh day if the ascent rate was faster, is recommended. As an adjunct to nifedipine, salmeterol can be added beginning 24 hours prior to ascent.

Phosphodiesterase inhibitors may be beneficial in the treatment of HAPE based on their physiologic effects of decreased pulmonary arterial pressures and pulmonary vasodilation.

When to Admit

- All patients with HACE or HAPE must be hospitalized for further observation.
- Hospitalization must also be considered for any patient who remains symptomatic after treatment and descent.
- Pulmonary symptoms and hypoxia may be worsened by complications requiring admission.

SAFETY OF AIR TRAVEL & SELECTION OF PATIENTS FOR AIR TRAVEL

The medical safety of air travel depends on the nature and severity of the traveler's preflight condition and factors such as travel duration and frequency of travel, use and frequency of in-flight exercise, cabin altitude pressure, availability of medical supplies, infectious diseases, and the presence of health care professionals on board. Air travel has been associated with an increased risk of transmission of infectious diseases. A WHO website includes the most updated information on travel health risks and infectious diseases (https://www.who.int/travel-advice). Flight crews and passengers are susceptible to a wide range of flight-related problems: pulmonary, VTE, infectious, cardiac, GI, ocular, immunologic, syncope, neuropsychiatric, metabolic, trauma, radiation, and substance-related conditions. Air travel risks are higher for air travelers with preexisting medical conditions.

Hypobaric hypoxia is the underlying etiology of most serious medical emergencies in-flight due to cabin altitude. Despite commercial aircraft pressurization requirements, there is significant hypoxemia, dyspnea, gas expansion, and stress in travelers, particularly in those with underlying pulmonary disease.

Any form of prolonged travel involving immobilization is associated with increased risk of VTE. Risks for VTE in long-distance travelers include the following: (1) travel time of 4 or more hours, (2) hypercoagulable disorders, and (3) acquired risks. VTE risk is more relevant for those with additional VTE risk factors. VTE prevention measures include wearing graduated compression stockings; frequent exercise and position changes during travel; and in high-risk travelers, the use of thromboprophylaxis, such as low-molecular-weight heparin or DOACs (see Chapter 16).

Air travel is not advised for anyone who is "incapacitated" or has any "unstable conditions." The Air Transport Association of America defines an incapacitated passenger as "one who is suffering from a physical or mental disability and who, because of such disability or the effect of the flight on the disability, is incapable of self-care; would endanger the health or safety of such person or other passengers or airline employees; or would cause discomfort or annoyance of other passengers." Unstable conditions include any condition requiring active treatment immediately.

Pregnancy

Pregnant travelers have unique travel-related and location-specific risks. A clinician's authorization is required if travel is essential during the ninth month of pregnancy or earlier in a complicated or high-risk pregnancy.

Long travel increases risk of VTE for the pregnant traveler. Pregnant travelers are also at higher risk from infection transmission and air travel radiation exposure.

Prevention

Air travel complications may be reduced by the following preventive measures: passenger prescreening, passenger education, and in-flight positioning and activity. Prescreening evaluation is recommended for all high-risk patients including preexisting requirement for oxygen, underlying lung disease, comorbidities worsened by hypoxemia, previous respiratory distress during air travel, recent pneumothorax, and recent (within 6 weeks) acute respiratory illness. Patients at risk for hypoxia must be assessed prior to air travel to determine if there is a need for supplemental in-flight oxygen.

Air travel education must include risk reduction for VTE, infectious diseases, and exacerbations of underlying medical conditions. Long-distance travelers can reduce VTE risk by avoiding constrictive clothing, staying well-hydrated, changing position frequently, avoiding cramped position and leg crossing, engaging in frequent (at least every hour) in-flight leg stretching exercises, and *walking for 5 minutes every hour*. Clinicians must assess those with high risk of VTE prior to air travel to determine whether anticoagulation is indicated (see Table 16–14).

43

Poisoning

Craig Smollin, MD

INITIAL EVALUATION: POISONING OR OVERDOSE

Patients with drug overdoses or poisoning may initially have no symptoms or they may have varying degrees of overt intoxication. The asymptomatic patient may have been exposed to or may have ingested a lethal dose, but not yet exhibit any manifestations of toxicity. It is important to *(1) quickly assess the potential danger, (2) consider gut and skin decontamination to prevent absorption, (3) treat complications if they occur, and (4) observe the asymptomatic patient for an appropriate interval.*

Assess the Danger

If the drug or poison is known, its danger can be assessed by consulting a text or computerized information resource or by calling a **regional poison control center.** (In the United States, dialing **1-800-222-1222** will direct the call to the regional poison control center.) Assessment considers the dose ingested; the time since ingestion; the presence of any symptoms or clinical signs; preexisting cardiac, respiratory, kidney, or liver disease; and, occasionally, specific serum drug or toxin levels. Be aware that the history given by the patient or family may be incomplete or unreliable.

IMMEDIATE 24-HOUR TOXICOLOGY CONSULTATION

Call your **regional poison control center**
U.S. toll-free **1-800-222-1222**

Observe the Patient

Asymptomatic or mildly symptomatic patients should be observed for at least 4–6 hours. Longer observation is indicated if the ingested substance is a sustained-release preparation or is known to slow GI motility (eg, opioids, anticholinergics, aspirin) or may cause a delayed onset of symptoms (eg, acetaminophen, colchicine, hepatotoxic mushrooms). After that time, the patient may be discharged if no symptoms have developed. *Before discharge, psychiatric evaluation should be performed to assess suicide risk.* Intentional ingestions in adolescents should raise the possibility of unwanted pregnancy or sexual abuse.

THE SYMPTOMATIC PATIENT

In symptomatic patients, treatment of life-threatening complications takes precedence over in-depth diagnostic evaluation. Patients with mild symptoms may deteriorate rapidly; therefore, *all potentially significant exposures should be observed in an acute care facility.* The following complications may occur, depending on the type of poisoning.

COMA

Assessment & Complications

Coma is commonly associated with ingestion of large doses of antihistamines (eg, diphenhydramine), benzodiazepines and other sedative-hypnotic drugs, ethanol, opioids, antipsychotic drugs, or antidepressants. The most common cause of death in comatose patients is respiratory failure, which may occur abruptly. Pulmonary aspiration of gastric contents may also occur, especially in patients who are deeply obtunded or convulsing. Hypoxia and hypoventilation may cause or aggravate hypotension, arrhythmias, and seizures. Thus, *protection of the airway and assisted ventilation are the most important treatment measures for any poisoned patient.*

Treatment

A. Emergency Management

The initial emergency management of coma can be remembered by the mnemonic *ABCD*, for Airway, *B*reathing, *C*irculation, and *D*rugs (thiamine, then dextrose and naloxone), respectively.

1. Airway—Establish a patent airway by positioning, suction, or insertion of an artificial nasal or oropharyngeal airway. If the patient is deeply comatose or if airway reflexes are depressed, perform endotracheal intubation. These airway interventions may not be necessary if the patient is intoxicated by an opioid and responds to intravenous naloxone.

2. Breathing—Clinically assess the quality and depth of respiration and provide assistance, if necessary, with a bag-valve-mask device or mechanical ventilator. Administer supplemental oxygen, if needed. The arterial or venous blood CO_2 tension, or noninvasive end-tidal CO_2 monitoring, is useful in determining the adequacy of ventilation. The arterial blood PO_2 determination may reveal hypoxemia, which may be caused by respiratory depression, bronchospasm, pulmonary aspiration, or noncardiogenic pulmonary edema. *Pulse oximetry provides an assessment of oxygenation but is unreliable in patients with methemoglobinemia or carbon monoxide poisoning.*

3. Circulation—Measure the pulse and blood pressure and estimate tissue perfusion (eg, by measurement of urinary output, skin signs, arterial blood pH). Place the patient on continuous ECG monitoring. Insert an intravenous line, and draw blood for glucose, electrolytes, serum creatinine and liver tests, and possible quantitative toxicologic testing.

4. Drugs—

A. DEXTROSE AND THIAMINE—Unless promptly treated, severe hypoglycemia can cause irreversible brain damage. Therefore, in all obtunded, comatose, or convulsing patients, give 50% dextrose, 50–100 mL by intravenous bolus, unless a rapid point-of-care blood glucose test rules out hypoglycemia. In patients with alcohol use disorder or malnourishment who may have marginal thiamine stores, give thiamine, 100 mg intramuscularly, *before* the dextrose, or in the intravenous fluids.

B. OPIOID ANTAGONISTS—Naloxone, 0.4–2 mg intravenously or 2–4 mg by intranasal spray, may reverse opioid-induced respiratory depression and coma. *It is often given empirically to any comatose patient with depressed respirations.* If opioid overdose is strongly suspected, give additional doses of naloxone (up to 5–10 mg may be required to reverse the effects of potent opioids). **Note:** *Naloxone has a shorter duration of action (2–3 hours) than most common opioids; repeated doses may be required, and continuous observation for at least 3–4 hours after the last dose is mandatory.*

C. FLUMAZENIL—Flumazenil, 0.2–0.5 mg intravenously, repeated as needed up to a maximum of 3 mg, may reverse benzodiazepine-induced coma. **Caution:** *In most circumstances, use of flumazenil is not advised as the potential risks outweigh its benefits.*

HYPOTHERMIA

Assessment & Complications

Hypothermia commonly accompanies coma due to opioids, ethanol, hypoglycemic agents, phenothiazines, barbiturates, benzodiazepines, and other sedative-hypnotics and CNS depressants. Hypothermic patients may have a barely perceptible pulse and blood pressure. Hypothermia may cause or aggravate hypotension, which will not reverse until the temperature is normalized.

Treatment

Treatment of hypothermia is discussed in Chapter 42. Gradual rewarming is preferred unless the patient is in cardiac arrest.

HYPOTENSION

Assessment & Complications

Hypotension may be due to poisoning by many different drugs, including antihypertensives, β-blockers, calcium channel blockers, disulfiram (ethanol interaction), iron, trazodone, quetiapine, and other antipsychotic agents and antidepressants. Poisons causing hypotension include cyanide, carbon monoxide, hydrogen sulfide, aluminum or zinc phosphide, arsenic, and certain mushrooms.

Hypotension in the poisoned or drug-overdosed patient may be caused by venous or arteriolar vasodilation, hypovolemia, depressed cardiac contractility, or a combination of these effects.

Treatment

Most hypotensive poisoned patients respond to empiric treatment with repeated 200 mL intravenous boluses of 0.9% saline or other isotonic crystalloid up to a total of 1–2 L; much larger amounts may be needed if the patient is profoundly volume-depleted (eg, as with massive diarrhea due to *Amanita phalloides* mushroom poisoning). Monitoring the CVP using bedside cardiac ultrasound can help determine whether further fluid therapy is needed. If fluid therapy is not successful after adequate volume replacement, give vasopressors by intravenous infusion.

Hypotension caused by certain toxins may respond to specific treatment. For hypotension caused by overdoses of tricyclic antidepressants or other sodium channel blockers, administer sodium bicarbonate, 50–100 mEq by intravenous bolus injection. Norepinephrine 4–8 mcg/min by intravenous infusion is more effective than dopamine in some patients with overdoses of tricyclic antidepressants or of drugs with predominantly vasodilating effects. For β-blocker overdose, glucagon (5–10 mg intravenously) may be of value. For calcium channel blocker overdose, administer calcium chloride, 1–2 g intravenously (repeated doses may be necessary; doses of 5–10 g and more have been given in some cases). High-dose insulin (0.5–1 U/kg/hour intravenously) euglycemic therapy may also be used (see the sections Beta-Adrenergic Blockers and Calcium Channel Blockers, below). Intralipid 20% lipid emulsion has been reported to improve hemodynamics in some cases of intoxication by highly lipid-soluble drugs such as bupivacaine, bupropion, clomipramine, and verapamil. Intravenous methylene blue and extracorporeal membrane oxygenation (ECMO) have been employed in some refractory cases; ECMO may offer temporary hemodynamic stabilization while the offending drug is eliminated.

Upchurch C et al. Extracorporeal membrane oxygenation use in poisoning: a narrative review with clinical recommendations. Clin Toxicol (Phila). 2021;59:877. [PMID: 34396873]

HYPERTENSION

Assessment & Complications

Hypertension may be due to poisoning with amphetamines and synthetic stimulants, anticholinergics, cocaine, performance-enhancing products (eg, containing caffeine, phenylephrine, ephedrine, or yohimbine), MAO inhibitors, and other drugs.

Severe hypertension (eg, diastolic blood pressure > 105–110 mm Hg in a person who does not have chronic hypertension) can result in acute intracranial hemorrhage, MI, or aortic dissection.

Treatment

Treat hypertension if the *patient is symptomatic or if the diastolic pressure is higher than 105–110 mm Hg*—especially if there is no prior history of hypertension.

Hypertensive patients who are agitated or anxious may benefit from a sedative (such as lorazepam, 2–3 mg intravenously) or an antipsychotic drug (eg, haloperidol or olanzapine). For persistent hypertension, administer phentolamine, 2–5 mg intravenously, or nitroprusside sodium, 0.25–8 mcg/kg/min intravenously. If excessive tachycardia is present, *add* esmolol, 25–100 mcg/kg/min intravenously, or labetalol, 0.2–0.3 mg/kg intravenously. **Caution:** *Do not give β-blockers alone, since doing so may paradoxically worsen hypertension in some cases as a result of unopposed α-adrenergic stimulation.*

ARRHYTHMIAS

Assessment & Complications

Arrhythmias may occur with a variety of drugs or toxins (Table 43–1). They may also occur from hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia, hypokalemia, hypomagnesemia, or hypocalcemia), or following exposure to chlorinated and fluorinated solvents and propellants. Polymorphic ventricular tachycardia (torsades de pointes) is often associated with drugs that prolong the QT interval.

Treatment

Hypoxia or electrolyte imbalance should be sought and treated. If ventricular arrhythmias persist, administer lidocaine or amiodarone at usual antiarrhythmic doses. **Note:** Wide QRS complex tachycardia in the setting of tricyclic antidepressant overdose (or diphenhydramine or class Ia antiarrhythmic drugs) should be treated with sodium bicarbonate, 50–100 mEq intravenously by bolus infusion. **Caution:** *In such cases, avoid class Ia antiarrhythmic agents (eg, procainamide, disopyramide) and amiodarone, which may aggravate arrhythmias caused by tricyclic antidepressants.* Torsades de pointes associated with prolonged QT interval may respond to intravenous magnesium (2 g intravenously over 2 minutes) or overdrive pacing. Treat digitalis-induced arrhythmias with digoxin-specific antibodies.

For tachyarrhythmias induced by chlorinated or fluorinated solvents, chloral hydrate, Freons, or sympathomimetic agents, use propranolol or esmolol (see doses in the Hypertension section, above).

Table 43–1. Common toxins or drugs causing arrhythmias (listed in alphabetical order by arrhythmia).[1]

Arrhythmia	Common Causes
Atrioventricular block	β-Blockers, calcium channel blockers, class Ia antiarrhythmics (including quinidine), carbamazepine, clonidine, digitalis glycosides, lithium
QT interval prolongation and torsades de pointes	Arsenic, class Ia and class III antiarrhythmics, citalopram, droperidol, lithium, methadone, pentamidine, sertraline, sotalol, and many other drugs[2]
Sinus bradycardia	β-Blockers, calcium channel blockers, clonidine, digitalis glycosides, organophosphates
Sinus tachycardia	β-Agonists (eg, albuterol), amphetamines, anticholinergics, antihistamines, caffeine, cocaine, pseudoephedrine, tricyclic and other antidepressants
Ventricular premature beats and ventricular tachycardia	Amphetamines, cocaine, ephedrine, caffeine, chlorinated or fluorinated hydrocarbons, digoxin, aconite (found in some Chinese herbal preparations), fluoride, theophylline. QT prolongation can lead to atypical ventricular tachycardia (torsades de pointes)
Wide QRS complex	Class Ia and class Ic antiarrhythmics, phenothiazines (eg, thioridazine), potassium (hyperkalemia), propranolol, tricyclic antidepressants, bupropion, lamotrigine, diphenhydramine (severe overdose)

[1] Arrhythmias may also occur as a result of hypoxia, metabolic acidosis, or electrolyte imbalance (eg, hyperkalemia or hypokalemia, hypocalcemia, hypomagnesemia).

[2] https://crediblemeds.org/

SEIZURES

Assessment & Complications

Seizures may be caused by many poisons and drugs, including amphetamines, antidepressants (especially tricyclic antidepressants, bupropion, and venlafaxine), antihistamines (especially diphenhydramine), antipsychotics, camphor, synthetic cannabinoids and cathinones, cocaine, isoniazid (INH), chlorinated insecticides, piperazines,

Table 43–2. Seizures related to toxins or drugs requiring special consideration (listed in alphabetical order by toxin or drug).[1]

Toxin or Drug	Comments
Isoniazid	Administer pyridoxine.
Lithium	May indicate need for hemodialysis.
Methylenedioxymethamphetamine (MDMA; "Ecstasy")	Seizures may also be due to hyponatremia or hyperthermia.
Organophosphates	Administer pralidoxime (2-PAM) and atropine in addition to usual anticonvulsants.
Strychnine	"Seizures" are actually spinally mediated muscle spasms and usually require neuromuscular paralysis and mechanical ventilation.
Theophylline	Seizures indicate need for hemodialysis.
Tricyclic antidepressants	Hyperthermia and cardiotoxicity are common complications of repeated seizures; paralyze early with neuromuscular blockers to reduce muscular hyperactivity.

[1] See text for dosages.

tramadol, and theophylline. The onset of seizures may be delayed for up to 18–24 hours after extended-released bupropion overdose.

Seizures may also be caused by hypoxia, hypoglycemia, hypocalcemia, hyponatremia, withdrawal from alcohol or sedative-hypnotics, head trauma, CNS infection, or idiopathic epilepsy.

Prolonged or repeated seizures may lead to hypoxia, metabolic acidosis, hyperthermia, and rhabdomyolysis.

Treatment

Administer lorazepam, 2–3 mg, or diazepam, 5–10 mg, intravenously, or—if intravenous access is not immediately available—midazolam, 5–10 mg intramuscularly. If convulsions continue, administer phenobarbital, 15–20 mg/kg slowly intravenously over no less than 30 minutes. (For drug-induced seizures, phenobarbital is the preferred agent.) Levetiracetam and propofol infusion have also been reported effective for some resistant drug-induced seizures.

Seizures due to a few drugs and toxins may require antidotes or other specific therapies (as listed in Table 43–2).

HYPERTHERMIA

Assessment & Complications

Hyperthermia may be associated with poisoning by amphetamines and other synthetic stimulants (cathinones, piperazines), atropine and other anticholinergic drugs, cocaine, salicylates, strychnine, 2,4-dinitrophenol, tricyclic antidepressants, and various other medications. Overdoses of serotonin reuptake inhibitors (eg, fluoxetine, paroxetine, sertraline) or their use in a patient taking an MAO inhibitor may cause agitation, hyperactivity, myoclonus, and hyperthermia (**"serotonin syndrome"**). Antipsychotic agents can cause rigidity and hyperthermia **(neuroleptic malignant syndrome)**. (See Chapter 28.) **Malignant hyperthermia** is a rare disorder associated with general anesthetic agents.

Hyperthermia is a rapidly life-threatening complication. Severe hyperthermia (temperature > 40–41°C) can rapidly cause brain damage and multiorgan failure, including rhabdomyolysis, AKI, and coagulopathy (see Chapter 42).

Treatment

Treat hyperthermia aggressively. Options for cooling include spraying the skin with tepid water, and high-volume fanning, or alternatively, placing the patient in an ice water bath (not simply applying ice to selected surfaces). If external cooling is not rapidly effective, as shown by a normal rectal temperature within 20–30 minutes, or if there is significant muscle rigidity or hyperactivity, induce neuromuscular paralysis with a nondepolarizing neuromuscular blocker (eg, rocuronium, vecuronium). Once paralyzed, the patient must be intubated and mechanically ventilated and sedated. While the patient is paralyzed, the absence of visible muscular convulsive movements may give the false impression that brain seizure activity has ceased; bedside electroencephalography may be useful in recognizing continued nonconvulsive seizures.

Dantrolene (2–5 mg/kg intravenously) may be effective for hyperthermia associated with muscle rigidity that does not respond to neuromuscular blockade (ie, malignant hyperthermia). Bromocriptine, 2.5–7.5 mg orally daily, has been recommended for neuroleptic malignant syndrome. Cyproheptadine, 4 mg orally every hour for three or four doses, or chlorpromazine, 25 mg intravenously or 50 mg intramuscularly, has been used to treat serotonin syndrome.

ANTIDOTES & OTHER TREATMENT

ANTIDOTES

Give an antidote (if available) when there is reasonable certainty of a specific diagnosis (Table 43–3). Be aware that some antidotes themselves may have serious side effects. The indications and dosages for specific antidotes are discussed in the respective sections for specific toxins.

Hon KL et al. Antidotes for childhood toxidromes. Drugs Context. 2021;10:2020-11-4. [PMID: 34122588]
Kaiser SK et al. The roles of antidotes in emergency situations. Emerg Med Clin North Am. 2022;40:381. [PMID: 35461629]

Table 43–3. Some toxic agents for which there are specific antidotes (listed in alphabetical order by toxic agent).[1]

Toxic Agent	Specific Antidote
Acetaminophen	*N*-acetylcysteine
Anticholinergics (eg, atropine)	Physostigmine
Anticholinesterases (eg, organophosphate pesticides)	Atropine and pralidoxime (2-PAM)
Benzodiazepines	Flumazenil (rarely used)[2]
Carbon monoxide	Oxygen (hyperbaric oxygen of uncertain benefit)
Cyanide	Sodium nitrite, sodium thiosulfate; hydroxocobalamin
Digitalis glycosides	Digoxin-specific Fab antibodies
Heavy metals (eg, lead, mercury, iron) and arsenic	Specific chelating agents
Isoniazid	Pyridoxine (vitamin B_6)
Methanol, ethylene glycol	Ethanol (ethyl alcohol) or fomepizole (4-methylpyrazole)
Opioids	Naloxone, nalmefene
Snake venom	Specific antivenin
Sulfonylurea oral hypoglycemic drugs	Glucose, octreotide

[1] See text for indications and dosages.

[2] May induce seizures in patients with preexisting seizure disorder, benzodiazepine addiction, or concomitant tricyclic antidepressant or other convulsant overdose. If seizures occur, diazepam and other benzodiazepine anticonvulsants will not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.

DECONTAMINATION OF THE SKIN

Corrosive agents rapidly injure the skin and eyes and must be removed immediately. In addition, many toxins are readily absorbed through the skin, and systemic absorption can be prevented only by rapid action.

Wash the affected areas with copious quantities of lukewarm water or saline, taking care to limit exposure to health care providers. Wash carefully behind the ears, under the nails, and in skin folds. For oily substances (eg, pesticides), wash the skin at least twice with plain soap and shampoo the hair. *Specific decontaminating solutions or solvents (eg, alcohol) are rarely indicated and in some cases may paradoxically enhance absorption.* For exposure to chemical warfare poisons such as nerve agents or vesicants, some authorities recommend use of a dilute hypochlorite solution (household bleach diluted 1:10 with water), but not in the eyes.

DECONTAMINATION OF THE EYES

Act quickly to prevent serious damage. Flush the eyes with copious amounts of saline or water. (If available, instill local anesthetic drops in the eye before beginning irrigation.) Remove contact lenses if present. Lift the tarsal conjunctiva to look for undissolved particles and to facilitate irrigation. Continue irrigation for 15 minutes or until each eye has been irrigated with at least 1 L of solution. If the toxin is an acid or a base, check the pH of the tears after irrigation, and continue irrigation until the pH is between 7 and 7.4. An amphoteric decontamination solution (Diphoterine, Prevor) is used in some countries for treatment of alkali injuries to the eye.

After irrigation is complete, perform a careful examination of the eye, using fluorescein and a slit lamp or Wood lamp to identify areas of corneal injury. Patients with serious conjunctival or corneal injury should be immediately referred to an ophthalmologist.

GASTROINTESTINAL DECONTAMINATION

Removal of ingested poisons by induced emesis or gastric lavage was a routine part of emergency treatment for decades. However, *prospective randomized studies have failed to demonstrate improved clinical outcome after gastric emptying.* For small or moderate ingestions of most substances, toxicologists often recommend oral **activated charcoal** alone without prior gastric emptying; in some cases, when the interval after ingestion has been > 1–2 hours and the ingestion is non–life-threatening, even charcoal is withheld (eg, if the estimated benefit is outweighed by the potential risk of pulmonary aspiration of charcoal). *Exceptions are large ingestions of anticholinergic compounds and salicylates, which often delay gastric emptying, and ingestion of sustained-release or enteric-coated tablets, which may remain intact for several hours. In these cases, delayed gut decontamination may be indicated.*

Gastric emptying is not generally used for ingestion of corrosive agents or petroleum distillates, because further esophageal injury or pulmonary aspiration may result. However, in certain cases, removal of the toxin may be more important than concern over possible complications. Consult a medical toxicologist or regional poison control center (1-800-222-1222) for advice.

A. Activated Charcoal

Activated charcoal effectively adsorbs almost all drugs and poisons. Poorly adsorbed substances include iron, lithium, potassium, sodium, mineral acids, and alcohols.

1. Indications—Activated charcoal can be used for prompt adsorption of drugs or toxins in the stomach and intestine. However, evidence of benefit in clinical studies is lacking. Administration of charcoal, especially if mixed with sorbitol, can provoke vomiting, which could lead to pulmonary aspiration in an obtunded patient.

2. Contraindications—Activated charcoal should *not* be used for comatose or convulsing patients unless it can be given by gastric tube and the airway is first protected by a cuffed endotracheal tube. It is also contraindicated for patients with ileus or intestinal obstruction or those who have ingested corrosives for whom endoscopy is planned.

3. Technique—Administer activated charcoal, 50–100 g orally or via gastric tube, mixed in aqueous slurry. Repeated doses may be given to ensure GI adsorption or to enhance elimination of some drugs.

B. Whole Bowel Irrigation

Whole bowel irrigation uses large volumes of a balanced polyethylene glycol-electrolyte solution to mechanically cleanse the entire intestinal tract. Because of the composition of the irrigating solution, there is no significant gain or loss of systemic fluids or electrolytes.

1. Indications—Whole bowel irrigation is particularly effective for massive iron ingestion in which intact tablets are visible on abdominal radiographs. It has also been used for ingestions of lithium, sustained-release and enteric-coated tablets, and swallowed drug-filled packets.

2. Contraindications—Do *not* use in patients with suspected intestinal obstruction. Use with caution in patients who are obtunded or have depressed airway protective reflexes.

3. Technique—Administer a balanced polyethylene glycol-electrolyte solution (CoLyte, GoLYTELY) into the stomach via gastric tube at a rate of 1–2 L/hour until the rectal effluent is clear. This may take several hours. It is most effective when patients can sit on a commode to pass the intestinal contents.

C. Increased Drug Removal

1. Urinary manipulation—*Forced diuresis is hazardous; the risk of complications (fluid overload, electrolyte imbalance) usually outweighs its benefits.* Some drugs (eg, salicylates, phenobarbital) are more rapidly excreted with an alkaline urine. To alkalinize the urine, add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.225% saline (¼ normal saline), and infuse this solution intravenously at a rate of about 150–200 mL/hour. Acidification (sometimes promoted for amphetamines, phencyclidine) is not effective and should *not* be used.

2. Hemodialysis—The indications for dialysis are as follows: (1) known or suspected potentially lethal amounts of a dialyzable drug (Table 43–4); (2) poisoning with deep coma, apnea, severe hypotension, fluid and electrolyte or acid-base disturbance, or extreme body temperature changes that cannot be corrected by conventional measures; or (3) poisoning in patients with severe kidney, cardiac, pulmonary, or hepatic disease who will not be able to eliminate toxin by the usual mechanisms.

Continuous renal replacement therapy (including continuous venovenous hemodiafiltration and similar techniques) may be of benefit for elimination of some poisons and has the advantage of gradual removal of the toxin and correction of any accompanying acidosis. Its use has been reported in the management of a variety of poisonings, including lithium intoxication. The *Extracorporeal Treatments in Poisoning (EXTRIP) workgroup* publishes valuable summary recommendations for several important dialyzable toxins (see https://www.extrip-workgroup.org/recommendations)

3. Repeat-dose charcoal—Repeated doses of activated charcoal, 20–30 g orally or via gastric tube every 3–4 hours, may hasten elimination of some drugs (eg, phenytoin, carbamazepine, dapsone) by absorbing drugs excreted into the gut lumen ("gut dialysis"). However, clinical studies have failed to prove better outcome using repeat-dose charcoal. *Sorbitol or other cathartics should not be used with each dose*, or else the resulting large stool volumes may lead to dehydration or hypernatremia.

Table 43–4. Recommended use of hemodialysis in selected poisonings (listed in alphabetical order).[1]

Poison	Common Indications[1]
Carbamazepine	Seizures, severe cardiotoxicity; serum level > 60 mg/L
Ethylene glycol	Acidosis, serum level > 50 mg/dL
Lithium	Severe symptoms; level > 4–5 mEq/L, especially if kidney impairment Note: dialysis of uncertain value; consult with medical toxicologist
Methanol	Acidosis, serum level > 50 mg/dL
Phenobarbital	Intractable hypotension, acidosis despite maximal supportive care
Salicylate	Severe acidosis, CNS symptoms, serum level > 100 mg/dL (acute overdose) or > 60 mg/dL (chronic intoxication)
Theophylline	Seizures, severe cardiotoxicity, serum level > 100 mg/L (acute overdose) or > 60 mg/L (chronic intoxication)
Valproic acid	Serum level > 900–1000 mg/L or deep coma, severe acidosis

[1] See text for further discussion of indications.

Hoegberg LCG et al. Systematic review on the use of activated charcoal for gastrointestinal decontamination following acute oral overdose. Clin Toxicol (Phila). 2021;59:1196. [PMID: 34424785]

DIAGNOSIS OF POISONING

The identity of the ingested substance or substances is usually known, but occasionally a comatose patient is found with an unlabeled container or the patient is unable or unwilling to give a coherent history. By performing a directed physical examination and ordering common clinical laboratory tests, the clinician can often make a tentative diagnosis that may allow empiric interventions or may suggest specific toxicologic tests.

Physical Examination

Important diagnostic variables in the physical examination include blood pressure, pulse rate, temperature, pupil size, sweating, muscle tone, level of consciousness, and the presence or absence of peristaltic activity. Poisonings may present with one or more of the following common syndromes.

A. Sympathomimetic Syndrome

The blood pressure and pulse rate are elevated, though with severe hypertension reflex bradycardia may occur.

The temperature is often elevated, pupils are dilated, and the skin is sweaty, though mucous membranes are dry. Patients are usually agitated, anxious, or frankly psychotic.

Examples: Amphetamines, cocaine, ephedrine, pseudoephedrine, synthetic cathinones, and cannabinoids.

B. Sympatholytic Syndrome

The blood pressure and pulse rate are decreased, and body temperature is low. The pupils are small or even pinpoint. Patients are usually obtunded or comatose.

Examples: Barbiturates, benzodiazepines and other sedative-hypnotics, γ-hydroxybutyrate (GHB), clonidine and related antihypertensives, ethanol, opioids.

C. Cholinergic Syndrome

Stimulation of *muscarinic receptors* causes bradycardia, miosis (constricted pupils), sweating, and hyperperistalsis as well as bronchorrhea, wheezing, excessive salivation, and urinary incontinence. *Nicotinic receptor* stimulation may produce initial hypertension and tachycardia as well as fasciculations and muscle weakness. Patients are usually agitated and anxious.

Examples: Carbamates, nicotine, organophosphates (including nerve agents), physostigmine.

D. Anticholinergic Syndrome

Tachycardia with mild hypertension is common, and the body temperature is often elevated. Pupils are widely dilated. The skin is flushed, hot, and dry. Peristalsis is decreased, and urinary retention is common. Patients may have myoclonic jerking or choreoathetoid movements. Agitated delirium is frequently seen, and severe hyperthermia may occur.

Examples: Atropine, scopolamine, other naturally occurring and pharmaceutical anticholinergics, antihistamines, tricyclic antidepressants.

Laboratory Tests

The following clinical laboratory tests are recommended for screening of the overdosed patient: measured serum osmolality and calculated osmol gap (if toxic alcohol ingestion is in the differential diagnosis), electrolytes and anion gap, glucose, creatinine, BUN, creatine kinase (CK), UA (eg, oxalate crystals with ethylene glycol poisoning, myoglobinuria with rhabdomyolysis), and ECG. *Quantitative serum acetaminophen and ethanol levels should be determined in all patients with drug overdoses as well as a serum or urine pregnancy test when appropriate.*

A. Osmol Gap

The osmol gap (Table 43–5) is increased in the presence of large quantities of low-molecular-weight substances, most commonly ethanol. Other common poisons associated with increased osmol gap are acetone, ethylene glycol, isopropyl alcohol, methanol, and propylene glycol. **Note:** Severe alcoholic ketoacidosis and diabetic ketoacidosis can also cause an elevated osmol gap resulting from the production of ketones and other low-molecular-weight substances.

Table 43–5. Use of the osmol gap in toxicology.

The osmol gap (Δ osm) is determined by subtracting the calculated serum osmolality from the measured serum osmolality.

$$\begin{array}{l}\text{Calculated}\\ \text{osmolality}\\ \text{(osm)}\end{array} = 2[\text{Na}^{+}(\text{mEq/L})] + \frac{\begin{array}{c}\text{Glucose}\\ (\text{mg/dL})\end{array}}{18} + \frac{\begin{array}{c}\text{BUN}\\ (\text{mg/dL})\end{array}}{2.8}$$

Δ osm = Measured osmolality − Calculated osmolality = 0 ± 10

Serum osmolality may be increased by contributions of exogenous substances such as alcohols and other low-molecular-weight substances. Since these substances are not included in the calculated osmolality, there will be a gap proportionate to their serum concentration. Contact a medical toxicologist or poison control center for assistance in calculating and interpreting the osmol gap.

Reproduced with permission from Stone CK, Humphries RL (editors): *Current Emergency Diagnosis & Treatment*, 5th ed. McGraw-Hill, 2004.

B. Anion Gap

Metabolic acidosis associated with an elevated anion gap is usually due to an accumulation of lactic acid or other acids (see Chapter 24). Common causes of elevated anion gap in poisoning include carbon monoxide, cyanide, ethylene glycol, propylene glycol, iron, INH, methanol, metformin, ibuprofen, and salicylates. Massive acetaminophen overdose can cause early-onset anion gap metabolic acidosis.

The osmol gap should also be checked; combined elevated anion and osmol gaps suggests poisoning by methanol or ethylene glycol, though this may also occur in patients with diabetic ketoacidosis and alcoholic ketoacidosis.

C. Toxicology Laboratory Testing

A comprehensive toxicology screen is of little value in the initial care of the poisoned patient because results usually do not return in time to influence clinical management. *Specific quantitative levels of certain drugs may be extremely helpful (Table 43–6), however, especially if specific antidotes or interventions (eg, dialysis) would be indicated based on the results.*

Many hospitals can perform a quick but limited urine screen for "drugs of abuse" (typically these screens include only opiates, amphetamines, and cocaine, and some add benzodiazepines, barbiturates, methadone, oxycodone, phencyclidine, and tetrahydrocannabinol [marijuana]). There are numerous false-positive and false-negative results. For example, synthetic opioids, such as fentanyl, oxycodone, and methadone, are often not detected by routine opiate immunoassays.

Abdominal Imaging

A plain film (or CT scan) of the abdomen may reveal radiopaque iron tablets, drug-filled condoms, or other toxic material. Studies suggest that few tablets are predictably visible (eg, ferrous sulfate, sodium chloride, calcium carbonate, and potassium chloride). Thus, the radiograph is useful only if abnormal.

Table 43–6. Specific quantitative levels and potential therapeutic interventions (listed in alphabetical order by drug or toxin).[1]

Drug or Toxin	Treatment
Acetaminophen	Specific antidote (*N*-acetylcysteine) based on serum level
Carbamazepine	High level may indicate need for hemodialysis
Carbon monoxide	High carboxyhemoglobin level indicates need for 100% oxygen, consideration of hyperbaric oxygen
Digoxin	On basis of serum digoxin level and severity of clinical presentation, treatment with Fab antibody fragments (eg, DigiFab) may be indicated
Ethanol	Low serum level may suggest nonalcoholic cause of coma (eg, trauma, other drugs, other alcohols); serum ethanol may also be useful in monitoring ethanol therapy for methanol or ethylene glycol poisoning
Iron	Level may indicate need for chelation with deferoxamine
Lithium	Serum levels can guide decision to institute hemodialysis
Methanol, ethylene glycol	Acidosis, high levels indicate need for hemodialysis, therapy with ethanol or fomepizole
Methemoglobin	Methemoglobinemia can be treated with methylene blue intravenously
Salicylates	High level may indicate need for hemodialysis, alkaline diuresis
Theophylline	Immediate hemodialysis or hemoperfusion may be indicated based on serum level
Valproic acid	Elevated levels may indicate need to consider hemodialysis or L-carnitine therapy, or both

[1] Some drugs or toxins may have profound and irreversible toxicity unless rapid and specific management is provided outside of routine supportive care. For these agents, laboratory testing may provide the serum level or other evidence required for administering a specific antidote or arranging for hemodialysis.

When to Refer

Consultation with a regional poison control center (1-800-222-1222) or a medical toxicologist is recommended when the diagnosis is uncertain; there are questions about what laboratory tests to order; when dialysis is being considered to remove the drug or poison; or when advice is needed regarding the indications, dose, and side effects of antidotes.

When to Admit

- The patient has symptoms and signs of intoxication that are not expected to clear within a 6- to 8-hour observation period.
- Delayed absorption of the drug might be predicted to cause a later onset of serious symptoms (eg, after ingestion of a sustained-release product).
- Continued administration of an antidote is required (eg, *N*-acetylcysteine for acetaminophen overdose).
- Psychiatric or social services evaluation is needed for suicide attempt or suspected drug abuse.

Olson KR, Smollin C (editors). *Poisoning & Drug Overdose*, 8th ed. McGraw-Hill, 2022.

SELECTED POISONINGS

ACETAMINOPHEN

Acetaminophen (paracetamol in the United Kingdom, Europe) is a common analgesic found in many nonprescription and prescription products. After absorption, it is metabolized mainly by glucuronidation and sulfation, with a small fraction metabolized via the P450 mixed-function oxidase system (2E1) to a highly toxic reactive intermediate. This toxic intermediate is normally detoxified by cellular glutathione. With acute acetaminophen overdose (> 150–200 mg/kg, or 8–10 g in an average adult), hepatocellular glutathione is depleted and the reactive intermediate attacks other cell proteins, causing necrosis. *Patients with enhanced P450 2E1 activity, such as patients who have alcohol use disorder and patients taking INH, are at increased risk for developing hepatotoxicity.* Hepatic toxicity may also occur after overuse of acetaminophen—eg, as a result of taking two or three acetaminophen-containing products concurrently or *exceeding the recommended maximum dose of 4 g/day for several days*. The amount of acetaminophen in US oral prescription combination products (eg, hydrocodone/acetaminophen) is limited by the FDA to no more than 325 mg per tablet.

Clinical Findings

Shortly after ingestion, patients may have nausea or vomiting, but there are usually no other signs of toxicity until 24–48 hours after ingestion, when hepatic aminotransferase levels begin to increase. With severe poisoning, fulminant hepatic necrosis may occur, resulting in jaundice, hepatic encephalopathy, AKI, and death. Rarely, massive ingestion (eg, serum levels > 500–1000 mg/L [33–66 mmol/L]) can cause early-onset acute coma, seizures, hypotension, and metabolic acidosis unrelated to hepatic injury.

The risk of hepatotoxicity after acute overdose is based on measurement of the serum acetaminophen level. An acute overdose is defined as an ingestion occurring within a 24-hour period. Plot the serum level versus the time since ingestion on the **acetaminophen nomogram** shown in Figure 43–1. Ingestion of sustained-release products or coingestion of an anticholinergic agent, salicylate, or opioid drug may cause delayed elevation of serum levels, which can make it difficult to interpret the nomogram. The nomogram cannot be used after chronic or staggered overdoses occurring over more than 24 hours.

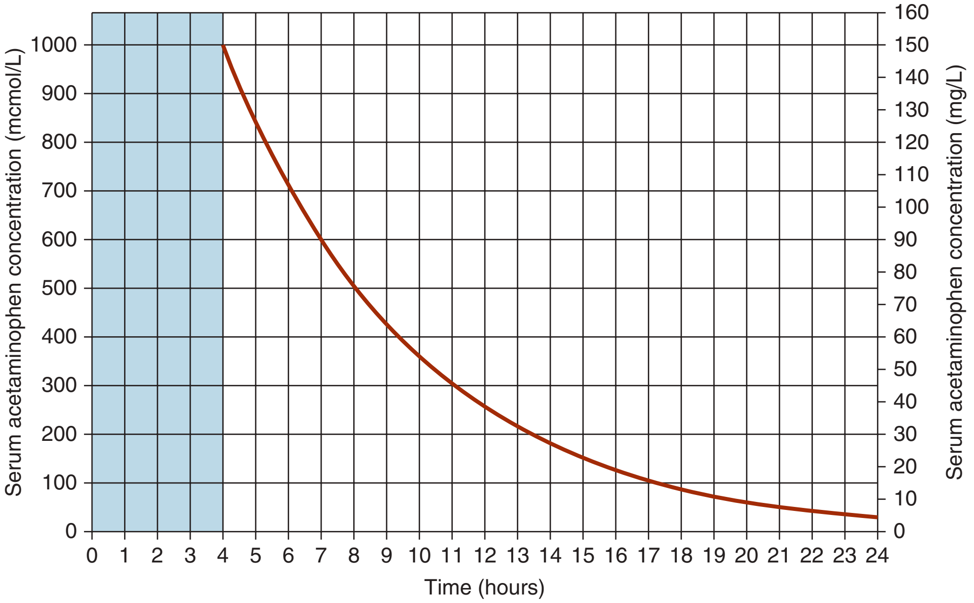

Figure 43–1. Nomogram for prediction of acetaminophen hepatotoxicity following acute overdosage. Patients with serum levels above the line after acute overdose should receive antidotal treatment. (Reproduced with permission from Daly FF, Fountain JS, Murray L, Graudins A, Buckley NA; Panel of Australian and New Zealand clinical toxicologists. Guidelines for the management of paracetamol poisoning in Australia and New Zealand—explanation and elaboration. A consensus statement from clinical toxicologists consulting to the Australasian poisons information centres. Med J Aust. 2008;188(5):296–301.)

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal if it can be given within 1–2 hours of the ingestion. Although charcoal may interfere with absorption of the oral preparation of the antidote acetylcysteine, this is not considered clinically significant.

B. Specific Treatment

If the serum or plasma acetaminophen level falls above the line on the nomogram (Figure 43–1), treatment with *N*-acetylcysteine is indicated; it can be given orally or intravenously. Oral treatment begins with a loading dose of *N*-acetylcysteine, 140 mg/kg, followed by 70 mg/kg every 4 hours. Dilute the solution to about 5% with water, juice, or soda. If vomiting interferes with oral *N*-acetylcysteine administration, consider giving the antidote intravenously. The conventional oral *N*-acetylcysteine protocol in the United States calls for 72 hours of treatment. However, other regimens have demonstrated equivalent success with 20–48 hours of treatment.

The FDA-approved 21-hour intravenous regimen of acetylcysteine (Acetadote) calls for a loading dose of 150 mg/kg given intravenously over 60 minutes, followed by a 4-hour infusion of 50 mg/kg, and a 16-hour infusion of 100 mg/kg. High-risk acetaminophen ingestions (reported ingestions of > 30 g or if the measured serum acetaminophen level is greater than twice the nomogram line) may require a higher dose of *N*-acetylcysteine, and providers should contact a regional poison control center or medical toxicologist for assistance. Novel simplified intravenous regimens are under investigation and may replace the traditional three-bag dosing described above.

Treatment with N-acetylcysteine is most effective if it is started within 8–10 hours after ingestion. Fomepizole, a cytochrome 2E1 inhibitor, has been proposed as an adjunctive therapy, but is not routinely used. Hemodialysis is rarely indicated but might be needed in some patients with massive overdose.

AMPHETAMINES & COCAINE

Amphetamines and cocaine are widely used for their euphorigenic and stimulant properties. Both drugs may be smoked, snorted, ingested, or injected. Amphetamines and cocaine produce CNS stimulation and a generalized increase in central and peripheral sympathetic activity. The toxic dose of each drug is highly variable and depends on the route of administration and individual tolerance. The onset of effects is most rapid after intravenous injection or smoking. Amphetamine derivatives and related drugs include methamphetamine ("crystal meth," "crank"), MDMA ("ecstasy"), ephedrine ("herbal ecstasy"), and methcathinone ("cat" or "khat"). Methcathinone derivatives and related synthetic chemicals such as methylenedioxypyrovalerone (MDPV) are popular drugs of abuse and are often sold as purported "bath salts." Amphetamine-like reactions have also been reported after use of synthetic cannabinoids (eg, "Spice" and "K2"). Nonprescription medications and nutritional supplements may contain stimulant or sympathomimetic drugs such as ephedrine, yohimbine, or caffeine (see also Theophylline & Caffeine section). *Increasingly, amphetamines and cocaine are adulterated with fentanyl or fentanyl analogs* resulting in unexpected coma, respiratory depression, and death (see also opioids section).

Clinical Findings

Presenting symptoms may include anxiety, tremulousness, tachycardia, hypertension, diaphoresis, dilated pupils, agitation, muscular hyperactivity, and psychosis. Muscle hyperactivity may lead to metabolic acidosis and rhabdomyolysis. In severe intoxication, seizures and hyperthermia may occur. Sustained or severe hypertension may result in intracranial hemorrhage, aortic dissection, or MI; chronic use may cause cardiomyopathy. Ischemic colitis has been reported. Hyponatremia has been reported after MDMA use; the mechanism is not known but may involve excessive water intake, syndrome of inappropriate ADH (SIADH), or both.

The diagnosis is supported by finding amphetamines or the cocaine metabolite benzoylecgonine in the urine. Note that many drugs can give false-positive results on the immunoassay for amphetamines, and most synthetic stimulants do not react with the immunoassay, giving false-negative results.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Treat seizures as described at the beginning of this chapter. Rapidly lower the body temperature in patients who are hyperthermic (temperature higher than 39–40°C). Give intravenous fluids to prevent myoglobinuric kidney injury in patients who have rhabdomyolysis.

B. Specific Treatment

Treat agitation, psychosis, or seizures with a benzodiazepine such as diazepam, 5–10 mg, or lorazepam, 2–3 mg intravenously. Add phenobarbital 15 mg/kg intravenously for persistent seizures. Treat hypertension with a vasodilator drug such as phentolamine (1–5 mg intravenously) or nitroprusside, or a combined α- and β-adrenergic blocker such as labetalol (10–20 mg intravenously). Do *not* administer a pure β-blocker such as propranolol alone, as this may result in paradoxical worsening of the hypertension due to unopposed α-adrenergic effects.

Treat tachycardia or tachyarrhythmias with a short-acting β-blocker such as esmolol (25–100 mcg/kg/min by intravenous infusion). Treat hyperthermia as described above. Treat hyponatremia as outlined in Chapter 24.

ANTICOAGULANTS

Warfarin and related compounds (including ingredients of many commercial rodenticides, the so-called *superwarfarins* such as brodifacoum, difenacoum, and related compounds) inhibit the normal clotting system by blocking hepatic synthesis of vitamin K–dependent clotting factors. After ingestion of "superwarfarins," inhibition of clotting factor synthesis may persist for several weeks or even months after a single dose. DOACs include the direct thrombin inhibitor dabigatran and the factor Xa inhibitors apixaban, edoxaban, and rivaroxaban. Some of these, especially dabigatran, are largely eliminated by the kidney and may accumulate in patients with kidney dysfunction.

Excessive anticoagulation may cause hemoptysis, gross hematuria, bloody stools, hemorrhages into organs, widespread bruising, and bleeding into joint spaces.

Treatment

A. Emergency and Supportive Measures

Discontinue the drug at the first sign of gross bleeding and determine the prothrombin time (INR). The prothrombin time is increased within 12–24 hours (peak 36–48 hours) after overdose of warfarin or "superwarfarins." **Note:** *DOACs (dabigatran, apixaban, edoxaban, and rivaroxaban) do not predictably alter routine coagulation studies (prothrombin time, partial thromboplastin time, and INR), and these tests are of limited use.* Specialized coagulation studies including the hemaclot and ecarin clotting assay and the anti-factor Xa activity may be helpful but are not widely available.

If the patient has ingested an acute overdose, administer activated charcoal.

B. Specific Treatment

1. Warfarin—*In cases of warfarin and "superwarfarin" overdose, do not treat prophylactically with vitamin K—*wait for evidence of anticoagulation (elevated prothrombin time). See Table 16–21 for the management of INR above therapeutic range. Doses of vitamin K as high as 200 mg/day have been required after ingestion of "superwarfarins." Give fresh-frozen plasma, prothrombin complex concentrate, or activated factor VII as needed to rapidly correct the coagulation factor deficit if there is serious bleeding. If the patient is chronically anticoagulated and has strong medical indications for being maintained in that status (eg, prosthetic heart valve), give much smaller doses of vitamin K (1 mg orally) and fresh-frozen plasma (or both) to titrate to the desired prothrombin time. If the patient has ingested brodifacoum or a related superwarfarin, prolonged observation (*over weeks*) and repeated administration of large doses of vitamin K may be required.

2. DOACs—Vitamin K does not reverse the anticoagulant effects of the DOACs. Idarucizumab has been approved by the FDA for reversal of the thrombin inhibitor dabigatran; andexanet is approved for reversal of the factor Xa inhibitors apixaban, edoxaban, and rivaroxaban. If specific reversal agents are unavailable, evidence supports the use of prothrombin complex concentrates or activated prothrombin complex concentrates for reversal of factor Xa inhibitors.

ANTIPSYCHOTIC DRUGS

Drugs in this group include "conventional" antipsychotics (eg, chlorpromazine, haloperidol, droperidol) and "atypical" antipsychotics (eg, risperidone, olanzapine, ziprasidone, quetiapine, aripiprazole). While conventional drugs act mainly on CNS dopamine receptors, atypical drugs also interact with serotonin receptors.

Therapeutic doses of conventional phenothiazines (particularly chlorpromazine) induce drowsiness and mild orthostatic hypotension in as many as 50% of patients. Larger doses can cause obtundation, miosis, severe hypotension, tachycardia, convulsions, and coma. Abnormal cardiac conduction may occur, resulting in prolongation of QRS or QT intervals (or both) and ventricular arrhythmias. Among the atypical agents, quetiapine is more likely to cause coma and hypotension. Hypotension is probably related to blockade of peripheral α-adrenergic receptors, causing vasodilatation.

With therapeutic or toxic doses, an acute extrapyramidal dystonic reaction may develop in some patients, with spasmodic contractions of the face and neck muscles, extensor rigidity of the back muscles, carpopedal spasm, and motor restlessness. This reaction is more common with haloperidol and other butyrophenones and less common with newer atypical antipsychotics. Severe rigidity accompanied by hyperthermia and metabolic acidosis (**neuroleptic malignant syndrome**) may occasionally occur and is life-threatening (see Chapter 28). Atypical antipsychotics have also been associated with weight gain and diabetes mellitus, including diabetic ketoacidosis.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal for large or recent ingestions. For severe hypotension, treatment with intravenous fluids and vasopressor agents may be necessary. Treat hyperthermia as outlined. Maintain ECG monitoring.

B. Specific Treatment

Hypotension often responds to intravenous saline boluses; cardiac arrhythmias associated with widened QRS intervals on the ECG may respond to intravenous sodium bicarbonate as is given for tricyclic antidepressant overdoses. Prolongation of the QT interval and torsades de pointes are usually treated with intravenous magnesium or overdrive pacing.

For extrapyramidal signs, give diphenhydramine, 0.5–1 mg/kg intravenously, or benztropine mesylate, 0.01–0.02 mg/kg intramuscularly. Treatment with oral doses of these agents should be continued for 24–48 hours.

Bromocriptine (2.5–7.5 mg orally daily) may be effective for mild or moderate neuroleptic malignant syndrome. Dantrolene (2–5 mg/kg intravenously) has also been used for muscle rigidity but is not a true antidote. For severe hyperthermia, perform rapid neuromuscular paralysis.

Campleman SL et al; Toxicology Investigators' Consortium (ToxIC). Drug-specific risk of severe QT prolongation following acute drug overdose. Clin Toxicol (Phila). 2020;58:1326. [PMID: 32252558]

ATROPINE & ANTICHOLINERGICS

Atropine, scopolamine, belladonna, *Datura stramonium, Hyoscyamus niger*, some mushrooms, tricyclic antidepressants, and antihistamines are antimuscarinic agents with variable CNS effects. Symptoms of toxicity include dryness of the mouth, thirst, difficulty in swallowing, and blurring of vision. Physical signs include dilated pupils, flushed skin, tachycardia, fever, delirium, myoclonus, and ileus. Antidepressants and antihistamines may also induce convulsions.

Antihistamines are commonly available with or without prescription. Diphenhydramine commonly causes delirium, tachycardia, and seizures. Massive diphenhydramine overdose may mimic tricyclic antidepressant cardiotoxic poisoning.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal. External cooling and sedation, or neuromuscular paralysis in rare cases, are indicated to control high temperatures.

B. Specific Treatment

For severe anticholinergic syndrome (eg, agitated delirium), give physostigmine salicylate, 0.5–1 mg slowly intravenously over 5 minutes, with ECG monitoring; repeat as needed to a total dose of no more than 2 mg. Oral rivastigmine 3–6 mg also can be used as an alternative. **Caution:** Bradyarrhythmias and convulsions are a hazard with physostigmine administration, and the drug should be *avoided* in patients with evidence of cardiotoxic effects (eg, QRS interval prolongation) from tricyclic antidepressants or other sodium channel blockers.

β-ADRENERGIC BLOCKERS

There are a wide variety of β-adrenergic blocking drugs, with varying pharmacologic and pharmacokinetic properties (see Table 13–10). *The most toxic β-blocker is propranolol, which not only blocks β_1- and β_2-adrenoceptors but also has direct membrane-depressant and CNS effects.*

Clinical Findings

The most common findings with mild or moderate intoxication are hypotension and bradycardia. Cardiac depression from more severe poisoning is often unresponsive to conventional therapy with β-adrenergic stimulants such as dopamine and norepinephrine. In addition, with propranolol and other lipid-soluble drugs, seizures and coma may occur. Propranolol, oxprenolol, acebutolol, and alprenolol also have membrane-depressant effects and can cause conduction disturbance (wide QRS interval) similar to tricyclic antidepressant overdose.

The diagnosis is based on typical clinical findings. Routine toxicology screening does not usually include β-blockers.

Treatment

A. Emergency and Supportive Measures

Attempts to treat bradycardia or heart block with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion, titrated to the desired heart rate), or an external transcutaneous cardiac pacemaker are often ineffective, and specific antidotal treatment may be necessary.

For drugs ingested within an hour of presentation (or longer after ingestion of an extended-release formulation), administer activated charcoal.

B. Specific Treatment

For persistent bradycardia and hypotension, give glucagon, 5–10 mg intravenously, followed by an infusion of 1–5 mg/hour. Glucagon is an inotropic agent that acts at a different receptor site and is therefore not affected by β-blockade. High-dose insulin (0.5–1 U/kg/hour intravenously) along with glucose supplementation has also been used to reverse severe cardiotoxicity. Membrane-depressant effects (wide QRS interval) may respond to boluses of sodium bicarbonate (50–100 mEq intravenously) as for tricyclic antidepressant poisoning. Vasopressors (norepinephrine and epinephrine) improve hemodynamics and likely survival in case series and animal studies. Intravenous lipid emulsion (Intralipid 20%, 1.5 mL/kg) has been used successfully in severe propranolol overdose. ECMO should be considered for refractory shock.

Isoardi KZ et al. A prospective study of acute propranolol overdose defining dose thresholds of severe toxicity (ATOM-9). Clin Toxicol (Phila). 2025;63:1. [PMID: 39655516]

CALCIUM CHANNEL BLOCKERS

In therapeutic doses, nifedipine, nicardipine, amlodipine, felodipine, isradipine, nisoldipine, and nimodipine act mainly on blood vessels, while verapamil and diltiazem act mainly on cardiac contractility and conduction. However, these selective effects can be lost after acute overdose. Patients may present with bradycardia, atrioventricular (AV) nodal block, hypotension, or a combination of these effects. Hyperglycemia is common due to blockade of insulin release. With severe poisoning, cardiac arrest may occur.

Treatment

A. Emergency and Supportive Measures

For ingested drugs, administer activated charcoal. In addition, whole bowel irrigation should be initiated as soon as possible *if the patient has ingested a sustained-release product.*

B. Specific Treatment

Treat symptomatic bradycardia with atropine (0.5–2 mg intravenously), isoproterenol (2–20 mcg/min by intravenous infusion), or a transcutaneous cardiac pacemaker. For hypotension, give calcium chloride 10%, 10 mL, or calcium gluconate 10%, 20 mL. Repeat the dose every 3–5 minutes. The optimum (or maximum) dose has not been established, but many toxicologists recommend raising the ionized serum calcium level to as much as twice the normal level. Calcium is most useful in reversing negative inotropic effects and is less effective for AV nodal blockade and bradycardia. High doses of insulin (0.5–1 U/kg intravenous bolus followed by 0.5–1 U/kg/hour infusion) along with sufficient dextrose to maintain euglycemia have been reported to be beneficial, but there are no controlled studies. Vasopressors (norepinephrine and epinephrine) should also be used for refractory hypotension and shock. Infusion of Intralipid 20% lipid emulsion has been reported to improve hemodynamics in animal models and case reports of calcium channel blocker poisoning. Methylene blue (1–2 mg/kg) was reported to reverse refractory shock due to profound vasodilation in a patient with amlodipine poisoning. Angiotensin II has also been reported to improve vasoplegic shock in case reports of amlodipine poisoning. ECMO has been recommended for refractory shock.

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless gas produced by the combustion of carbon-containing materials. Poisoning may occur as a result of *suicidal or accidental exposure* to automobile exhaust, smoke inhalation in a fire, or accidental exposure to an improperly vented gas heater, generator, or other appliance. Carbon monoxide can be generated during degradation of some anesthetic gases by carbon dioxide adsorbents. Carbon monoxide avidly binds to hemoglobin, with an affinity approximately 250 times that of oxygen. This results in reduced oxygen-carrying capacity and altered delivery of oxygen to cells (see also Smoke Inhalation in Chapter 9).

Clinical Findings

At low carbon monoxide levels (carboxyhemoglobin saturation 10–20%), patients may have headache, dizziness, abdominal pain, and nausea. With higher levels, confusion, dyspnea, and syncope may occur. Hypotension, coma, and seizures are common with levels > 50–60%. Survivors of acute severe poisoning may develop permanent obvious or subtle neurologic and neuropsychiatric deficits. The fetus and newborn may be more susceptible because of high carbon monoxide affinity for fetal hemoglobin.

Carbon monoxide poisoning should be suspected in any person with severe headache or acutely altered mental status, especially during cold weather, when improperly vented heating systems may have been used. Diagnosis depends on specific measurement of the arterial or venous carboxyhemoglobin saturation, although the level may have declined if high-flow oxygen therapy has already been administered, and levels do not always correlate with clinical symptoms. *Routine ABG testing and pulse oximetry are* ***not*** *useful because they give falsely normal* PaO_2 *and oxyhemoglobin saturation determinations, respectively.* (Some specialized pulse oximetry devices are capable of distinguishing oxyhemoglobin from carboxyhemoglobin with variable accuracy.)

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist ventilation, if necessary. Remove the patient from exposure. Treat patients with coma, hypotension, or seizures as described at the beginning of this chapter.

B. Specific Treatment

The half-life of the carboxyhemoglobin (CoHb) complex is about 4–5 hours in room air but is reduced dramatically by high concentrations of oxygen. Administer 100% oxygen by tight-fitting high-flow reservoir face mask or endotracheal tube. *Hyperbaric oxygen (HBO)* can provide 100% oxygen under higher than atmospheric pressures, further shortening the half-life; it may also reduce the incidence of subtle neuropsychiatric sequelae. Randomized controlled studies disagree about the benefit of HBO, but commonly recommended indications for HBO in patients with carbon monoxide poisoning include a history of loss of consciousness, CoHb > 25%, metabolic acidosis, age over 50 years, and cerebellar findings on neurologic examination.

COCAINE

See Amphetamines & Cocaine.

ETHANOL, BENZODIAZEPINES, & OTHER SEDATIVE-HYPNOTIC AGENTS

The group of agents known as sedative-hypnotic drugs includes a variety of products used for the treatment of anxiety, depression, insomnia, and epilepsy. Besides common benzodiazepines, such as lorazepam, alprazolam, clonazepam, diazepam, oxazepam, chlordiazepoxide, and triazolam, this group includes the newer benzodiazepine-like hypnotics zolpidem, zopiclone, and zaleplon, the muscle relaxants baclofen and carisoprodol, and barbiturates such as phenobarbital. Toxicity and fatal overdoses from novel designer benzodiazepines (eg, etizolam, bromazolam), often coingested with fentanyl, are increasingly reported. Phenibut, a $GABA_B$ agonist, is associated with CNS depression and a withdrawal syndrome. Ethanol and other selected agents are also popular recreational drugs. All of these drugs depress the CNS reticular activating system, cerebral cortex, and cerebellum.

Clinical Findings

Mild intoxication produces euphoria, slurred speech, and ataxia. Ethanol intoxication may produce hypoglycemia, even at relatively low concentrations, in children and in fasting adults. With more severe intoxication, stupor, coma, and respiratory arrest may occur. Carisoprodol (Soma) commonly causes muscle jerking or myoclonus. *Death or serious morbidity is usually the result of pulmonary aspiration of gastric contents.* Bradycardia, hypotension, and hypothermia are common. Patients with massive intoxication may appear to be dead, with no reflex responses and even absent electroencephalographic activity. Diagnosis and assessment of severity of intoxication are usually based on clinical findings. Ethanol serum levels > 300 mg/dL (0.3 g/dL; 65 mmol/L) can produce coma in infrequent drinkers, while regular drinkers may remain awake at much higher levels.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal if the patient has ingested a massive dose and the airway is protected. Repeat-dose charcoal may enhance elimination of phenobarbital, but it has not been proved to improve clinical outcome. Hemodialysis may be necessary for patients with severe phenobarbital intoxication.

B. Specific Treatment

Flumazenil is a benzodiazepine receptor-specific antagonist; it has no effect on ethanol, barbiturates, or other sedative-hypnotic agents. If used, flumazenil is given slowly intravenously, 0.2 mg over 30–60 seconds, and repeated in 0.2–0.5 mg increments as needed up to a total dose of 3–5 mg. **Caution:** *Flumazenil should rarely be used because it may induce seizures in patients with preexisting seizure disorder, benzodiazepine tolerance, or concomitant tricyclic antidepressant or other convulsant overdose*. If seizures occur, diazepam and other benzodiazepine anticonvulsants may not be effective. As with naloxone, the duration of action of flumazenil is short (2–3 hours) and resedation may occur, requiring repeated doses.

γ-HYDROXYBUTYRATE (GHB)

GHB is a popular recreational drug. It originated as a short-acting general anesthetic and is occasionally used in the treatment of narcolepsy. It gained popularity among bodybuilders for its alleged growth hormone stimulation and found its way into social settings, where it is consumed as a liquid. It has been used to facilitate sexual assault (the *"date-rape" drug*). Symptoms after ingestion include drowsiness and lethargy followed by coma with respiratory depression. Muscle twitching and seizures are sometimes observed. Recovery is usually rapid, with patients awakening within a few hours. Other related chemicals with similar effects include butanediol and γ-butyrolactone (GBL). A prolonged withdrawal syndrome has been described in some heavy users.

Treatment

Monitor the airway and assist breathing if needed. There is no specific treatment. Most patients recover rapidly with supportive care. GHB withdrawal syndrome may require very large doses of benzodiazepines; baclofen has also been used.

HYPOGLYCEMIC DRUGS

Medications used for diabetes mellitus include insulin, sulfonylureas and other insulin secretagogues, α-glucosidase inhibitors (acarbose, miglitol), biguanides (metformin), thiazolidinediones (pioglitazone, rosiglitazone), sodium glucose transporter (SGLT-2) inhibitors, and peptide analogs (pramlintide, exenatide) or enhancers (sitagliptin) (see Chapter 32). Of these, insulin and the insulin secretagogues are the most likely to cause hypoglycemia. Metformin can cause lactic acidosis, especially in patients with impaired kidney function or after intentional drug overdose. Euglycemic diabetic ketoacidosis has been reported with SGLT-2 use. Table 32–5 lists the duration of hypoglycemic effect of oral hypoglycemic agents and Table 32–6 the extent and duration of various types of insulins.

Clinical Findings

Hypoglycemia may occur quickly after injection of short-acting insulins or may be delayed and prolonged, especially if a large amount has been injected into a single area, creating a "depot" effect. Hypoglycemia after sulfonylurea ingestion is usually apparent within a few hours but may be delayed several hours, especially if food or glucose-containing fluids have been given.

Treatment

Give sugar and carbohydrate-containing food or liquids by mouth, or intravenous dextrose if the patient is unable to swallow safely. For severe hypoglycemia, start with D50W, 50 mL intravenously (25 g dextrose); repeat, if needed. Follow up with dextrose-containing intravenous fluids (D5W or D10W) to maintain a blood glucose > 70–80 mg/dL.

For hypoglycemia caused by sulfonylureas and related insulin secretagogues, consider use of octreotide, a synthetic somatostatin analog that blocks pancreatic insulin release. A dose of 50–100 mcg octreotide subcutaneously every 6–12 hours can reduce the need for exogenous dextrose and prevent rebound hypoglycemia from excessive dextrose dosing.

Admit all patients with symptomatic hypoglycemia after sulfonylurea overdose. Observe asymptomatic overdose patients for at least 12 hours.

Consider hemodialysis for patients with metformin overdose accompanied by severe lactic acidosis (lactate > 20 mmol/L or pH < 7.0).

Baumgartner K et al. Toxicology of medications for diabetes mellitus. Crit Care Clin. 2021;37:577. [PMID: 34053707]

LEAD

Lead is used in a variety of industrial and commercial products, such as firearms ammunition, storage batteries, solders, paints, pottery, plumbing, and gasoline and is found in some traditional Latino/Latina and Ayurvedic ethnic medicines. *Lead toxicity usually results from chronic repeated exposure and is rare after a single ingestion.* Lead produces a variety of adverse effects on cellular function and primarily affects the nervous system, GI tract, and hematopoietic system.

Clinical Findings

Lead poisoning often goes undiagnosed initially because presenting symptoms and signs are nonspecific and exposure is not suspected. Common symptoms include colicky abdominal pain, constipation, headache, and irritability. Severe poisoning may cause coma and convulsions. Chronic intoxication can cause learning disorders (in children) and motor neuropathy (eg, wrist drop). Lead-containing bullet fragments in or near joint spaces can result in chronic lead toxicity.

Diagnosis is based on measurement of the blood lead level. Whole blood lead levels above 3.5 mcg/dL warrant public health investigation. Levels between 1 and 25 mcg/dL have been associated with subclinical impaired neurobehavioral development in children. Levels of 25–60 mcg/dL may be associated with headache, irritability, subclinical neuropathy, slowed reaction time and other neuropsychiatric effects. Levels of 60–80 mcg/dL are associated with moderate toxicity, and levels > 80–100 mcg/dL are often associated with severe poisoning. Other laboratory findings of lead poisoning include microcytic anemia with basophilic stippling and elevated free erythrocyte protoporphyrin.

Treatment

A. Emergency and Supportive Measures

The most critical intervention in the treatment of lead poisoning is identification of and removal from the source of exposure. For patients with encephalopathy, maintain a patent airway and treat coma and convulsions as described at the beginning of this chapter.

For recent acute ingestion, if a large lead-containing object (eg, fishing weight) is still visible in the stomach on abdominal radiograph, whole bowel irrigation, endoscopy, or even surgical removal may be necessary to prevent subacute lead poisoning. (The acidic gastric contents may corrode the metal surface, enhancing lead absorption. Once the object passes into the small intestine, the risk of toxicity declines.)

The US Occupational Safety and Health Administration establishes workplace standards for lead exposure. Contact the regional office for more information. Several states mandate reporting of cases of confirmed lead poisoning.

B. Specific Treatment

The indications for chelation depend on the blood lead level and the patient's clinical state. A medical toxicologist or regional poison control center (1-800-222-1222) should be consulted for advice about selection and use of these antidotes.

1. Severe toxicity—Patients with severe intoxication (encephalopathy or levels > 70–100 mcg/dL) should receive edetate calcium disodium (ethylenediaminetetraacetic acid, EDTA), 1500 mg/m^2/kg/day (approximately 50 mg/kg/day) in four to six divided doses or as a continuous intravenous infusion. Some clinicians also add dimercaprol (BAL), 4–5 mg/kg intramuscularly every 4 hours for 5 days, for patients with encephalopathy.

2. Less severe toxicity—Patients with less severe symptoms and asymptomatic patients with blood lead levels between 45 and 69 mcg/dL may be treated with edetate calcium disodium alone in dosages as above. An oral chelator, succimer (DMSA), is available for use in patients with mild to moderate intoxication. The usual dose is 10 mg/kg orally every 8 hours for 5 days, then every 12 hours for 2 weeks.

LSD & OTHER HALLUCINOGENS

A variety of substances—ranging from naturally occurring plants and mushrooms to synthetic substances such as phencyclidine (PCP), toluene and other solvents, dextromethorphan, and lysergic acid diethylamide (LSD)—are used for their hallucinogenic properties. The mechanism of toxicity and the clinical effects vary for each substance.

Many hallucinogenic plants and mushrooms produce anticholinergic delirium, characterized by flushed skin, dry mucous membranes, dilated pupils, tachycardia, and urinary retention. Other plants and mushrooms may contain hallucinogenic indoles such as mescaline, psilocybin, and LSD, which typically cause marked visual hallucinations and perceptual distortion, widely dilated pupils, and mild tachycardia. PCP and ketamine are antagonists of NMDA receptors and produce an acute dissociative state often associated with vertical and horizontal nystagmus. Both ketamine and psilocybin increasingly are used to treat chronic pain, depression, and PTSD. Toluene and other hydrocarbon solvents (eg, butane, trichloroethylene, "chemo," etc.) cause euphoria and delirium and may sensitize the myocardium to the effects of catecholamines, leading to fatal dysrhythmias. Other drugs used for their psychostimulant effects include synthetic cannabinoid receptor agonists, *Salvia divinorum*, synthetic tryptamines, and phenylethylamines, and mephedrone and related cathinone derivatives. See https://www.erowid.org/psychoactives/psychoactives.shtml for descriptions of various hallucinogenic substances.

Treatment

A. Emergency and Supportive Measures

Maintain a patent airway and assist respirations if necessary. Treat coma, hyperthermia, hypertension, and seizures as outlined at the beginning of this chapter. For recent large ingestions, consider giving activated charcoal orally or by gastric tube.

B. Specific Treatment

Patients with anticholinergic delirium may benefit from a dose of physostigmine, 0.5–1 mg intravenously, not to exceed 1 mg/min. Dysphoria, agitation, and psychosis associated with LSD or mescaline intoxication may respond to benzodiazepines (eg, lorazepam, 1–2 mg orally or intravenously) or haloperidol (2–5 mg intramuscularly or intravenously) or another antipsychotic drug (eg, olanzapine or ziprasidone). Monitor patients who have sniffed solvents for cardiac dysrhythmias (most commonly premature ventricular contractions, ventricular tachycardia, ventricular fibrillation); treatment with β-blockers such as propranolol (1–5 mg intravenously) or esmolol (250–500 mcg/kg intravenously, then 50 mcg/kg/min by infusion) may be more effective than lidocaine or amiodarone.

MARIJUANA & SYNTHETIC CANNABINOIDS

Marijuana refers to the crushed dried leaves and flowers of the *Cannabis* plant. These dried leaves and flowers contain the psychoactive cannabinoid Δ-9-tetrahydrocannabinal (THC), which binds to endogenous cannabinoid receptors. Marijuana is usually smoked in cigarettes or pipes but may also be vaporized or added to a variety of foods, beverages, and candies. Resin from the plant may be dried and pressed into blocks called hashish, and solvents may be used to extract THC into highly concentrated oils (butane hash oil). THC is used medically as an appetite stimulant, as an antiemetic, and in the treatment of a variety of medical conditions. It has now been legalized for both medical and recreational use in an increasing number of US states (https://disa.com/map-of-marijuana-legality-by-state). Toxicity is dose dependent but varies significantly by individual, prior experience, and degree of tolerance. Synthetic cannabinoids ("Spice," "K2," "Black Mamba") are laboratory designed analogs of THC. They have become increasingly popular and are associated with a variety of adverse side effects, including seizures, kidney dysfunction, and serious neuropsychiatric symptoms. Cannabidiol (CBD) is a constituent of *Cannabis* that does not produce THC-like intoxication. CBD extracts are available over the counter and via the internet for a variety of proposed effects (anti-inflammatory, antioxidant, anxiolysis) and by prescription for some pediatric seizure disorders. Overdoses are typically not dangerous.

Clinical Findings

Onset of symptoms after smoking is usually rapid (minutes) with a duration of effect of approximately 2 hours. Symptoms may be delayed after ingestion and can result in prolonged intoxication (up to 8 hours). Mild intoxication may result in euphoria, palpitations, heightened sensory awareness, altered time perception, and sedation. More severe intoxication may result in anxiety, visual hallucinations, and acute paranoid psychosis. Physical findings include tachycardia, orthostatic hypotension, conjunctival injection, incoordination, slurred speech, and ataxia. Long-term heavy marijuana use is associated with recurrent nausea, abdominal pain, and vomiting, termed the **cannabinoid hyperemesis syndrome**. Children may inadvertently be exposed to marijuana through the consumption of THC-containing candies or other foods. Children may experience more severe symptoms including stupor, coma, and seizures. **E-cigarette or vaping-associated acute lung injury** is a syndrome of diffuse lung injury associated with vaping THC adulterated with vitamin E acetate.

Treatment

A. Emergency and Supportive Measures

Treat anxiety and paranoia with simple reassurance and placement into a calming environment. Benzodiazepines such as lorazepam or diazepam may be used for more severe behavioral and psychomotor symptoms. Hypotension and sinus tachycardia should be treated with intravenous fluids.

B. Specific Treatment

There is no specific antidote available. Consider activated charcoal early after ingestion of large quantities. Topical capsaicin and haloperidol have been used with variable success for the treatment of acute vomiting in patients with cannabinoid hyperemesis syndrome.

METHANOL & ETHYLENE GLYCOL

Methanol (wood alcohol) is commonly found in a variety of products, including solvents, duplicating fluids, record cleaning solutions, and paint removers. It is sometimes ingested intentionally by patients with alcohol use disorder as a substitute for ethanol and may also be found as a contaminant in home-brewed alcohols. Ethylene glycol is the major constituent in most antifreeze compounds. The toxicity of both agents is caused by metabolism to highly toxic organic acids—methanol to formic acid; ethylene glycol to glycolic and oxalic acids. Diethylene glycol is a nephrotoxic solvent that has been improperly substituted for glycerin in various liquid medications (cough syrup, teething medicine, acetaminophen), causing numerous deaths, including in Gambia in 2022.

Clinical Findings

Shortly after ingestion of methanol or ethylene glycol, patients usually appear “drunk.” Serum osmolality (measured by freezing point depression) is usually increased, but acidosis is often absent early. After several hours, metabolism to toxic organic acids leads to a severe anion gap metabolic acidosis, tachypnea, confusion, convulsions, and coma. Methanol intoxication frequently causes visual disturbances, while ethylene glycol often produces oxalate crystalluria and AKI. **Note:** Point-of-care analytical devices commonly used in the emergency department may falsely measure glycolic acid (a toxic metabolite of ethylene glycol) as lactic acid.

Treatment

A. Emergency and Supportive Measures

For patients presenting within 30–60 minutes after ingestion, empty the stomach by aspiration through a nasogastric tube. Charcoal is not very effective but should be administered if other poisons or drugs have also been ingested.

B. Specific Treatment

Patients with significant toxicity (manifested by severe metabolic acidosis, altered mental status, markedly elevated osmol gap, or evidence of end-organ toxicity) should undergo hemodialysis as soon as possible to remove the parent compound and the toxic metabolites. Treatment with folic acid, thiamine, and pyridoxine may enhance the breakdown of toxic metabolites.

Ethanol blocks metabolism of the parent compounds by competing for the enzyme alcohol dehydrogenase. Fomepizole (4-methylpyrazole; Antizol) blocks alcohol dehydrogenase and is much easier to use than ethanol. If started before onset of acidosis, fomepizole may be used as the sole treatment for ethylene glycol ingestion in some cases. A regional poison control center (1-800-222-1222) should be contacted for indications and dosing.

METHEMOGLOBINEMIA-INDUCING AGENTS

A large number of chemical agents are capable of oxidizing ferrous hemoglobin to its ferric state (methemoglobin), a form that cannot carry oxygen. Drugs and chemicals known to cause methemoglobinemia include benzocaine (a local anesthetic found in some topical anesthetic sprays and a variety of nonprescription products), aniline, propanil (an herbicide), nitrites, nitrogen oxide gases, nitrobenzene, dapsone, phenazopyridine (Pyridium), and many others. Dapsone has a long elimination half-life and may produce prolonged or recurrent methemoglobinemia. Amyl nitrite and isobutyl nitrite (“poppers”) are inhaled as sexual stimulants but can result in methemoglobinemia. Intentional ingestion of sodium nitrite is used increasingly as a method of suicide.

Clinical Findings

Methemoglobinemia reduces oxygen-carrying capacity and may cause dizziness, nausea, headache, dyspnea, confusion, seizures, and coma. The severity of symptoms depends on the percentage of hemoglobin oxidized to methemoglobin; severe poisoning is usually present when methemoglobin fractions are > 40–50%. Even at low levels

(15–20%), patients appear cyanotic because of the "chocolate brown" color of methemoglobin, but they have normal PO_2 results on ABG determinations. *Conventional pulse oximetry gives inaccurate oxygen saturation measurements*; the reading is often between 85% and 90%. Severe metabolic acidosis may be present. Hemolysis may occur, especially in patients susceptible to oxidant stress (ie, those with glucose-6-phosphate dehydrogenase deficiency).

Treatment

A. Emergency and Supportive Measures

Administer high-flow oxygen. If the causative agent was recently ingested, administer activated charcoal. Repeat-dose activated charcoal may enhance dapsone elimination.

B. Specific Treatment

Methylene blue enhances the conversion of methemoglobin to hemoglobin by increasing the activity of the enzyme methemoglobin reductase. For symptomatic patients, administer 1–2 mg/kg (0.1–0.2 mL/kg of 1% solution) intravenously. The dose may be repeated once in 15–20 minutes if necessary. Patients with hereditary methemoglobin reductase deficiency or glucose-6-phosphate dehydrogenase deficiency may not respond to methylene blue treatment. In severe cases where methylene blue is not available or is not effective, exchange blood transfusion may be necessary.

MUSHROOMS

There are thousands of mushroom species that cause a variety of toxic effects. The most dangerous species of mushrooms are *Amanita phalloides* and related species, which contain potent cytotoxins (amatoxins). Ingestion of even a portion of one amatoxin-containing mushroom may be sufficient to cause death.

The characteristic pathologic finding in fatalities from amatoxin-containing mushroom poisoning is acute massive necrosis of the liver.

Clinical Findings

Amatoxin-containing mushrooms typically cause a delayed onset (8–12 hours after ingestion) of severe abdominal cramps, vomiting, and profuse diarrhea, followed in 1–2 days by AKI, hepatic necrosis, and hepatic encephalopathy. *Cooking the mushrooms does not prevent poisoning.*

Monomethylhydrazine poisoning (*Gyromitra* and *Helvella* species) is more common following ingestion of uncooked mushrooms, as the toxin is water-soluble. Vomiting, diarrhea, hepatic necrosis, convulsions, coma, and hemolysis may occur after a latent period of 8–12 hours.

Treatment

A. Emergency Measures

After the onset of symptoms, efforts to remove the toxic agent are probably useless, especially in cases of amatoxin or gyromitrin poisoning, where there is usually a delay of 8–12 hours or more before symptoms occur and patients seek medical attention. However, activated charcoal is recommended for any recent ingestion of an unidentified or potentially toxic mushroom. Administer intravenous fluids liberally to replace massive losses from vomiting and diarrhea; monitor CVP, urinary output, and kidney function tests to help guide volume replacement.

B. Specific Treatment

A variety of purported antidotes (eg, thioctic acid, penicillin, corticosteroids) have been suggested for amatoxin-type mushroom poisoning, but controlled studies are lacking and experimental data in animals are equivocal. *Aggressive fluid replacement for diarrhea and intensive supportive care for hepatic failure are the mainstays of treatment*. Silymarin (silibinin), a derivative of milk thistle, is commonly used in Europe, but is commercially available in the United States only as an oral nutritional supplement. The European intravenous product (Legalon-SIL) can be obtained in the United States under an emergency IND provided by the FDA. Contact the regional poison control center (1-800-222-1222) for more information. *N*-Acetylcysteine has also been used and may provide some benefit. Liver transplant may be the only hope for survival in gravely ill patients—contact a liver transplant center early.

Tan JL et al. Amanitin intoxication: effects of therapies on clinical outcomes—a review of 40 years of reported cases. Clin Toxicol (Phila). 2022;60:1251. [PMID: 36129244]

OPIATES & OPIOIDS

Prescription and illicit opiates and opioids (eg, morphine, heroin, codeine, oxycodone, fentanyl, hydromorphone) are popular drugs of misuse and abuse and the cause of frequent hospitalizations for overdose. These drugs have widely varying potencies and durations of action; for example, *some of the illicit fentanyl derivatives are up to 2000 times more potent than morphine*. The opioid epidemic in the United States has become increasingly dangerous due to the presence of fentanyl as a replacement or adulterant in the heroin, cocaine, and other drugs sold illegally. *Users of illicit drugs are advised to assume there is fentanyl in any drug not sold by a pharmacy.* Overdose deaths involving synthetic opioids increased during the COVID-19 pandemic and pose a significant public health concern. All of these agents decrease CNS activity and sympathetic outflow by acting on opiate receptors in the brain. Tramadol is an analgesic that is unrelated chemically to opioids but acts on opioid receptors. Buprenorphine is a partial agonist-antagonist opioid used for the outpatient treatment of both chronic pain and opioid addiction (see Table 5–6). Kratom (*Mitragyna speciosa*) is an herbal supplement with agonist activity at mu opioid receptors. While it has been marketed as a "safe" and natural treatment for patients with opioid use disorder, overdose is associated with both agitation and drowsiness and in severe cases seizures, hallucinations, and respiratory depression.

Clinical Findings

Mild intoxication is characterized by euphoria, drowsiness, and constricted pupils. More severe intoxication may cause hypotension, bradycardia, hypothermia, coma, and respiratory arrest. Pulmonary edema may occur. Death is usually due to apnea or pulmonary aspiration of gastric contents. Methadone may cause QT interval prolongation and torsades de pointes. While the duration of effect for heroin is usually 3–5 hours, methadone intoxication may last for 48–72 hours or longer. Tramadol, dextromethorphan, and meperidine also occasionally cause seizures. With meperidine, the metabolite normeperidine is probably the cause of seizures and is most likely to accumulate with repeated dosing in patients with CKD. Wound botulism has been associated with skin-popping, especially involving "black tar" heroin. Buprenorphine added to an opioid regimen may precipitate acute withdrawal symptoms. Many opioids, including fentanyl, tramadol, oxycodone, and methadone, are not detected on routine urine toxicology "opiate" screening.

Treatment

A. Emergency and Supportive Measures

Protect the airway and assist ventilation. Administer activated charcoal for recent large ingestions.

B. Specific Treatment

Naloxone is a specific opioid antagonist, available without prescription in the United States, that can rapidly reverse signs of narcotic intoxication. Although it is structurally related to opioids, it has no agonist effects of its own. If no intravenous access is available, administer naloxone, 4 mg intranasally, otherwise administer 0.2–2 mg intravenously and repeat as needed to awaken the patient and maintain airway protective reflexes and spontaneous breathing. Large doses (up to 10 mg) may be required for patients intoxicated by some opioids (eg, codeine, fentanyl derivatives). **Caution:** *The duration of effect of naloxone is only about 2–3 hours; repeated doses may be necessary for patients intoxicated by long-acting drugs such as methadone. Continuous observation for at least 3 hours after the last naloxone dose is mandatory.* The immediate post-overdose period is an important opportunity to discuss harm reduction measures (take-home naloxone, fentanyl testing strips, safe injection practices) and to consider initiation of medications for opioid use disorder (buprenorphine, methadone).

PESTICIDES: CHOLINESTERASE INHIBITORS

Organophosphorus and carbamate insecticides (organophosphates: parathion, malathion, etc; carbamates: carbaryl, aldicarb, etc) are widely used in commercial agriculture and home gardening and have largely replaced older, more environmentally persistent organochlorine compounds such as DDT and chlordane. The organophosphates and carbamates—also called anticholinesterases because they inhibit the enzyme acetylcholinesterase—cause an increase in acetylcholine activity at nicotinic and muscarinic receptors and in the peripheral and CNS. There are a variety of chemical agents in this group, with widely varying potencies. Most of them are poorly water-soluble, are often formulated with an aromatic hydrocarbon solvent such as xylene, and are well absorbed through intact skin. Most chemical warfare "nerve agents" (such as GA [tabun], GB [sarin], GD [soman], and VX) are organophosphates.

Clinical Findings

Inhibition of cholinesterase results in abdominal cramps, diarrhea, vomiting, excessive salivation, sweating, lacrimation, miosis, wheezing and bronchorrhea, seizures, and skeletal muscle weakness. Initial tachycardia is usually followed by bradycardia. Profound skeletal muscle weakness, aggravated by excessive bronchial secretions and wheezing, may result in respiratory arrest and death. Symptoms and signs of poisoning may persist or recur over several days, especially with highly lipid-soluble agents such as fenthion or dimethoate.

The diagnosis should be suspected in patients who present with miosis, sweating, and diarrhea. Serum and RBC cholinesterase activity is usually depressed at least 50% below baseline in those patients who have severe intoxication.

Treatment

A. Emergency and Supportive Measures

If the agent was recently ingested, consider gut decontamination by aspiration of the liquid using a nasogastric tube followed by administration of activated charcoal. If the agent is on the person's skin or hair, wash repeatedly with soap or shampoo and water. Providers should take care to avoid skin exposure by wearing gloves and waterproof aprons. Dilute hypochlorite solution (eg, household bleach diluted 1:10) is reported to help break down organophosphate pesticides and nerve agents on equipment or clothing.

B. Specific Treatment

Atropine reverses excessive muscarinic stimulation and is effective for treatment of salivation, bronchial hypersecretion, wheezing, abdominal cramping, and sweating. However, it does not interact with nicotinic receptors at autonomic ganglia and at the neuromuscular junction and has no direct effect on muscle weakness. Administer 2 mg intravenously, and if there is no response after 5 minutes, give repeated boluses in rapidly escalating doses (eg, doubling the dose each time) as needed to dry bronchial secretions and decrease wheezing; as much as several hundred milligrams of atropine have been given to treat severe poisoning.

Pralidoxime (2-PAM, Protopam) is a more specific antidote that reverses organophosphate binding to the cholinesterase enzyme; therefore, it should be effective at the neuromuscular junction as well as other nicotinic and muscarinic sites. It is most likely to be clinically effective if started very soon after poisoning, to prevent permanent binding of the organophosphate to cholinesterase. However, clinical studies have yielded conflicting results regarding the effectiveness of pralidoxime in reducing mortality. Administer 1–2 g intravenously as a loading dose and begin a continuous infusion (200–500 mg/hour, titrated to clinical response). Continue to give pralidoxime as long as there is any evidence of acetylcholine excess. Pralidoxime is of questionable benefit for carbamate poisoning because carbamates have only a transitory effect on the cholinesterase enzyme. Other, unproven therapies for organophosphate poisoning include magnesium, sodium bicarbonate, clonidine, and extracorporeal removal.

Kharel H et al. The efficacy of pralidoxime in the treatment of organophosphate poisoning in humans: a systematic review and meta-analysis of randomized controlled trials. Cureus. 2020;12:e7174. [PMID: 32257715]

SALICYLATES

Salicylates (aspirin, methyl salicylate, bismuth subsalicylate, etc) are found in a variety of over-the-counter and prescription medications. Salicylates uncouple cellular oxidative phosphorylation, resulting in anaerobic metabolism and excessive production of lactic acid and heat, and they also interfere with several Krebs cycle enzymes. A *single ingestion of > 200 mg/kg of salicylate is likely to produce significant acute intoxication.* Poisoning may also occur as a result of *chronic excessive dosing* over several days. Although the half-life of salicylate is 2–3 hours after small doses, it may increase to 20 hours or more in patients with intoxication.

Clinical Findings

Acute ingestion often causes nausea and vomiting, occasionally with gastritis. Moderate intoxication is characterized by hyperpnea (deep and rapid breathing), tachycardia, tinnitus, and elevated anion gap metabolic acidosis. (A normal anion gap sometimes occurs due to salicylate interference with the chemistry analyzer, falsely raising the measured chloride.) Serious intoxication may result in agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, and death. The prothrombin time is often elevated owing to salicylate-induced hypoprothrombinemia. CNS intracellular glucose depletion can occur despite normal measured serum glucose levels.

Diagnosis of salicylate poisoning is suspected in any patient with metabolic acidosis and is confirmed by measuring the serum salicylate level. Patients with levels > 100 mg/dL (1000 mg/L or 7.2 mcmol/L) after an acute overdose are more likely to have severe poisoning. On the other hand, patients with subacute or chronic intoxication may suffer severe symptoms with levels of only 60–70 mg/dL (4.3–5 mcmol/L). The ABG typically reveals respiratory alkalosis with an underlying metabolic acidosis.

Treatment

A. Emergency and Supportive Measures

Administer activated charcoal orally. Gastric lavage followed by administration of extra doses of activated charcoal may be needed in patients who ingest > 10 g of aspirin. The desired ratio of charcoal to aspirin is about 10:1 by weight; while this cannot always be given as a single dose, it may be administered over the first 24 hours in divided doses every 2–4 hours along with whole bowel irrigation. Give glucose-containing fluids to reduce the risk of cerebral hypoglycemia. Treat metabolic acidosis with intravenous sodium bicarbonate. This is critical because acidosis (especially acidemia, pH < 7.40) promotes greater entry of salicylate into cells, worsening toxicity. **Warning:** *Sudden and severe deterioration can occur after rapid sequence intubation and controlled ventilation if the pH is allowed to fall due to hypercarbia during the apneic period.*

B. Specific Treatment

Alkalinization of the urine enhances renal salicylate excretion by trapping the salicylate anion in the urine. Add 100 mEq (two ampules) of sodium bicarbonate to 1 L of 5% dextrose in 0.2% saline and infuse this solution intravenously at a rate of about 150–200 mL/hour. Unless the patient is oliguric or hyperkalemic, add 20–30 mEq of potassium chloride to each liter of intravenous fluid. Patients who are volume-depleted often fail to produce an alkaline urine (paradoxical aciduria) unless potassium is given.

Hemodialysis may be lifesaving and is indicated for patients with severe metabolic acidosis, markedly altered mental status, or significantly elevated salicylate levels (eg, > 100 mg/dL [1000 mg/L or 7.2 mcmol/L] after acute overdose or > 60 mg/dL [600 mg/L or 4.3 mcmol/L] with subacute or chronic intoxication).

SEAFOOD POISONINGS

A variety of intoxications may occur after eating certain types of fish or other seafood. These include scombroid, ciguatera, paralytic shellfish, and puffer fish poisoning. The mechanisms of toxicity and clinical presentations are described in Table 43–7. In most cases, the seafood has a normal appearance and taste (scombroid may have a peppery taste).

Treatment

A. Emergency and Supportive Measures

Caution: *Abrupt respiratory arrest may occur in patients with acute paralytic shellfish and puffer fish poisoning.* Observe patients for at least 4–6 hours. Replace fluid and electrolyte losses from gastroenteritis with intravenous saline or other crystalloid solution.

For recent ingestions, it may be possible to adsorb residual toxin in the gut with activated charcoal, 50–60 g orally.

B. Specific Treatment

There is no specific antidote for paralytic shellfish or puffer fish poisoning.

1. Ciguatera—There are anecdotal reports of successful treatment of acute neurologic symptoms with mannitol, 1 g/kg intravenously, but this approach is not widely accepted. Gabapentin, 400 mg three times daily, may also relieve neuropathic symptoms.

2. Scombroid—Antihistamines such as diphenhydramine, 25–50 mg intravenously, and the H_2-blocker cimetidine, 300 mg intravenously, are usually effective.

SNAKE BITES

The venom of poisonous snakes and lizards may be predominantly **neurotoxic** (coral snake) or predominantly **cytolytic** (rattlesnakes, other pit vipers). Neurotoxins cause respiratory paralysis; cytolytic venoms cause tissue destruction by digestion and hemorrhage due to hemolysis and destruction of the endothelial lining of the blood vessels. The manifestations of rattlesnake envenomation are mostly local pain, redness, swelling, and extravasation of blood. Perioral tingling, metallic taste, nausea and vomiting, hypotension, and coagulopathy may also occur. Thrombocytopenia can persist for several days after a rattlesnake bite.

Table 43–7. Common seafood poisonings (listed in alphabetical order).

Type of Poisoning	Mechanism	Clinical Presentation
Ciguatera	Reef fish ingest toxic dinoflagellates, whose toxins accumulate in fish meat. Commonly implicated fish in the United States are barracuda, jack, snapper, and grouper.	1–6 hours after ingestion, people develop abdominal pain, vomiting, and diarrhea accompanied by a variety of neurologic symptoms, including paresthesias, reversal of hot and cold sensation, vertigo, headache, and intense itching. Autonomic disturbances, including hypotension and bradycardia, may occur.
Paralytic shellfish poisoning	Dinoflagellates produce saxitoxin, which is concentrated by filter-feeding mussels and clams. Saxitoxin blocks sodium conductance and neuronal transmission in skeletal muscles.	Onset is usually within 30–60 minutes. Initial symptoms include perioral and intraoral paresthesias. Other symptoms include nausea and vomiting, headache, dizziness, dysphagia, dysarthria, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.
Puffer fish poisoning	Tetrodotoxin is concentrated in liver, gonads, intestine, and skin. Toxic effects are similar to those of saxitoxin. Tetrodotoxin is also found in some North American newts and Central American frogs.	Onset is usually within 30–40 minutes but may be as short as 10 minutes. Initial perioral paresthesias are followed by headache, diaphoresis, nausea, vomiting, ataxia, and rapidly progressive muscle weakness that may result in respiratory arrest.
Scombroid	Improper preservation of large fish results in bacterial degradation of histidine to histamine. Commonly implicated fish include tuna, mahimahi, bonita, mackerel, and kingfish.	Allergic-like (anaphylactoid) symptoms are due to histamine, usually begin within 15–90 minutes, and include skin flushing, itching, urticaria, angioedema, bronchospasm, and hypotension as well as abdominal pain, vomiting, and diarrhea.

Neurotoxic envenomation may cause ptosis, dysphagia, diplopia, and respiratory arrest.

Treatment

A. Emergency and Supportive Measures

Immobilize the patient and the bitten part in a neutral position. *Avoid manipulation of the bitten area.* Transport the patient to a medical facility for definitive treatment. Do *not* give alcoholic beverages or stimulants; do *not* apply ice; do *not* apply a tourniquet. The potential trauma to underlying tissues resulting from incision and suction is not justified in view of the small amount of venom that can be recovered.

B. Specific Antidote and General Measures

1. Pit viper (eg, rattlesnake) envenomation—There are two commercially available antivenins for rattlesnake envenomation (CroFab and Anavip). Depending on the severity of symptoms CroFab is administered in increments of 4–6 vials by slow intravenous drip in 250–500 mL saline. For more serious envenomation with marked local effects and systemic toxicity (eg, hypotension, coagulopathy), higher doses and additional vials may be required. The dosing of Anavip is 10 vials by slow intravenous infusion over 60 minutes initially followed by additional 10-vial increments as needed for more serious envenomations or for progression of symptoms. Monitor vital signs and the blood coagulation profile. Type and cross-match blood. The adequacy of venom neutralization is indicated by improvement in symptoms and signs, and the rate that swelling slows. Prophylactic antibiotics are not indicated after a rattlesnake bite.

2. Elapid (coral snake) envenomation—Give 3–5 vials of specific antivenom (Micuris Fulvis Antivenon) as soon as possible. To locate antisera for this or exotic snakes, call a regional poison control center (1-800-222-1222).

SPIDER BITES & SCORPION STINGS

Envenomation from most species of spiders in the United States causes only local pain, redness, and swelling. The more venomous black widow spiders (*Latrodectus mactans*) cause generalized muscular pains, muscle spasms, and rigidity. The brown recluse spider (*Loxosceles reclusa*) causes progressive local necrosis as well as hemolytic reactions (rare).

Stings by most scorpions in the United States cause only local pain. Stings by the more toxic *Centruroides* species (found in the southwestern United States) may cause muscle cramps, twitching and jerking, and occasionally hypertension, convulsions, and pulmonary edema. Stings by scorpions from other parts of the world are not discussed here.

Treatment

A. Black Widow Spider Bites

Pain may be relieved with parenteral opioids or muscle relaxants (eg, methocarbamol, 15 mg/kg). Calcium gluconate 10%, 0.1–0.2 mL/kg intravenously, may transiently relieve muscle rigidity, although its effectiveness is unproven. *Latrodectus* antivenom is possibly more effective, but because of concerns about acute hypersensitivity reactions (horse serum–derived), it is often reserved for very young persons, older adults, or those who do not respond promptly to the above measures. Horse serum sensitivity testing is required. (Instruction and testing materials are included in the antivenin kit.)

B. Brown Recluse Spider Bites

Because bites occasionally progress to extensive local necrosis, some authorities recommend early excision of the bite site, whereas others use oral corticosteroids. Anecdotal reports have claimed success with dapsone and colchicine. All of these treatments remain unproven.

C. Scorpion Stings

No specific treatment other than analgesics is required for envenomations by most scorpions found in the United States. An FDA-approved specific antivenom is available for *Centruroides* stings.

THEOPHYLLINE & CAFFEINE

Methylxanthines, including theophylline and caffeine, are nonselective adenosine receptor antagonists. In overdose, toxicity results from the release of endogenous catecholamines with β_1- and β_2-adrenergic stimulation. Theophylline may cause intoxication after an acute single overdose, or intoxication may occur as a result of chronic accidental repeated overmedication or reduced elimination resulting from hepatic dysfunction or interacting drug (eg, cimetidine, erythromycin). The usual serum half-life of theophylline is 4–6 hours, but this may increase to > 20 hours after overdose. Caffeine in energy drinks or herbal or dietary supplement products can produce similar toxicity.

Clinical Findings

Mild intoxication causes nausea, vomiting, tachycardia, and tremulousness. Severe intoxication is characterized by ventricular and supraventricular tachyarrhythmias, hypotension, and seizures. *Status epilepticus is common and often intractable to the usual anticonvulsants.* After acute overdose (but not chronic intoxication), hypokalemia, hyperglycemia, and metabolic acidosis are common. Seizures and other manifestations of toxicity may be delayed for several hours after acute ingestion, especially if a sustained-release preparation such as Theo-Dur was taken.

Diagnosis is based on measurement of the serum theophylline concentration. Seizures and hypotension are likely to develop in acute overdose patients with serum levels > 100 mg/L (555 mcmol/L). Serious toxicity may develop at lower levels (ie, 40–60 mg/L [222–333 mcmol/L]) in patients with chronic intoxication. Serum caffeine levels are not routinely available in clinical practice, but in a study of 51 fatal cases the median level was 180 mg/L (range, 33–567 mg/L).

Treatment

A. Emergency and Supportive Measures

After acute ingestion, administer activated charcoal. Repeated doses of activated charcoal may enhance theophylline and caffeine elimination by "gut dialysis." Addition of whole bowel irrigation should be considered for large ingestions involving sustained-release preparations.

Hemodialysis is effective in removing theophylline and is indicated for patients with status epilepticus or markedly elevated serum theophylline levels (eg, > 100 mg/L [555 mcmol/L] after acute overdose or > 60 mg/L [333 mcmol/L] with chronic intoxication). It has also been used in caffeine overdose. Extracorporeal membrane oxygenation (ECMO) has been used successfully in hemodynamic collapse after caffeine overdose.

B. Specific Treatment

Treat seizures with benzodiazepines (lorazepam, 2–3 mg intravenously, or diazepam, 5–10 mg intravenously) or phenobarbital (10–15 mg/kg intravenously). Phenytoin is not effective. Hypotension and tachycardia—which are mediated through excessive β-adrenergic stimulation—may respond to β-blocker therapy even in low doses. Administer esmolol, 25–50 mcg/kg/min by intravenous infusion, or propranolol, 0.5–1 mg intravenously.

TRICYCLIC & OTHER ANTIDEPRESSANTS

Tricyclic and related cyclic antidepressants are among the most dangerous drugs involved in suicidal overdose. These drugs have anticholinergic and cardiac depressant properties ("quinidine-like" sodium channel blockade). Tricyclic antidepressants produce more marked membrane-depressant cardiotoxic effects than the phenothiazines.

Newer-generation antidepressants such as trazodone, fluoxetine, citalopram, paroxetine, sertraline, bupropion, venlafaxine, and fluvoxamine are not chemically related to the tricyclic antidepressant agents and, with the exception of bupropion, do not generally produce quinidine-like cardiotoxic effects. However, they may cause seizures in overdoses and serotonin syndrome.

Clinical Findings

Signs of severe intoxication may occur abruptly and without warning within 30–60 minutes after acute tricyclic overdose. Anticholinergic effects include dilated pupils, tachycardia, dry mouth, flushed skin, muscle twitching, and decreased peristalsis. Quinidine-like cardiotoxic effects include QRS interval widening (> 0.12 seconds; Figure 43–2), ventricular arrhythmias, AV block, and hypotension. Rightward-axis deviation of the terminal 40 milliseconds of the QRS has also been described. Prolongation of the QT interval and torsades de pointes

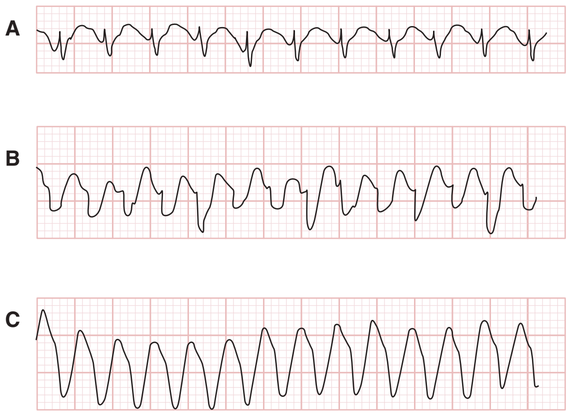

Figure 43–2. **Cardiac arrhythmias resulting from tricyclic antidepressant overdose. A: Delayed intraventricular conduction results in prolonged QRS interval (0.18 seconds). B and C: Supraventricular tachycardia with progressive widening of QRS complexes mimics ventricular tachycardia.** (Reproduced with permission from Benowitz NL, Goldschlager N. Cardiac disturbances in the toxicologic patient. In: Haddad LM, Winchester JF [editors], *Clinical Management of Poisoning and Drug Overdose*, 3rd edition. Saunders/Elsevier, 1998.)

have been reported with several of the newer antidepressants. Seizures and coma are common with severe intoxication. Life-threatening hyperthermia may result from status epilepticus and anticholinergic-induced impairment of sweating. Among newer agents, bupropion and venlafaxine have been associated with a greater risk of seizures.

The diagnosis should be suspected in any overdose patient with anticholinergic side effects, especially if there is widening of the QRS interval or seizures. For intoxication by most tricyclic antidepressants, *the QRS interval correlates with the severity of intoxication more reliably than the serum drug level.*

Serotonin syndrome should be suspected if agitation, delirium, diaphoresis, tremor, hyperreflexia, clonus (spontaneous, inducible, or ocular), and fever develop in a patient taking serotonin reuptake inhibitors.

Treatment

A. Emergency and Supportive Measures

Observe patients for at least 6 hours and admit all patients with evidence of anticholinergic effects (eg, delirium, dilated pupils, tachycardia) or signs of cardiotoxicity.

Administer activated charcoal and consider gastric lavage after recent large ingestions. All of these drugs have large volumes of distribution and are not effectively removed by hemodialysis procedures.

B. Specific Treatment

Cardiotoxic sodium channel–depressant effects of tricyclic antidepressants may respond to boluses of sodium bicarbonate (50–100 mEq intravenously). Sodium bicarbonate provides a large sodium load that alleviates depression of the sodium-dependent channel. Reversal of acidosis may also have beneficial effects at this site. Maintain the pH between 7.45 and 7.50. Alkalinization does not promote excretion of tricyclic antidepressants. Prolongation of the QT interval or torsades de pointes is usually treated with intravenous magnesium or overdrive pacing. Severe cardiotoxicity in patients with overdoses of lipid-soluble drugs (eg, amitriptyline, bupropion) has reportedly responded to intravenous lipid emulsion (Intralipid), 1.5 mL/kg repeated one or two times if needed. Plasma exchange using albumin and ECMO have been reported to be successful in several cases.

Mild serotonin syndrome may be treated with benzodiazepines and withdrawal of the antidepressant. Moderate cases may respond to cyproheptadine (4 mg orally or via gastric tube hourly for three or four doses) or chlorpromazine (25 mg intravenously). Severe hyperthermia should be treated with neuromuscular paralysis and endotracheal intubation in addition to external cooling measures.

INTRODUCTION TO CANCER

Etiology

Cancer is the second most common cause of death in the United States. In 2024, an estimated 2,001,140 cases of cancer were diagnosed, and 611,720 persons died of cancer. Table 44–1 lists the 10 leading cancer types in men and women by site. However, *death rates from cancers are declining*. Compared with the 1991 overall cancer death rate of 215 per 100,000 population, the 2016–2020 rate of 149.4 per 100,000 represents a 31% reduction in the overall cancer death rate. Importantly, death rates have declined in all four of the most common cancer types (prostate, breast, lung, and colorectum). Reductions in cancer mortality reflect successful implementation of a broad strategy of prevention, detection, and treatment. Due to these improvements, *the number of cancer survivors is increasing*. In 2022, an estimated 18.1 million people in the United States were alive in whom cancer had been previously diagnosed, approximately 5.4% of the population.

Modifiable Risk Factors

Tobacco use is the most common preventable cause of cancer death; at least 30% of all cancer deaths in the United States are directly linked to tobacco use. Clear evidence links tobacco use to at least 12 cancers. The most dramatic link is with lung cancer; > 80% of lung cancer deaths are attributable to smoking.

In 2023, the United States Department of Health and Human Services reported that 20% of adults in the United States were active tobacco users, a reduction from the 1955 peak of 57% for men and the 1965 peak of 34% for women. Cigarettes are the most common form of tobacco used in the United States, but among US youth, electronic cigarettes are the most popular form. From the Annual National Youth Tobacco Survey, the percent of middle and high school students in the United States who used e-cigarettes in 2024 was 5.9%, a decrease from 7.7% the year prior.

Tobacco cessation directed toward the individual should start with clinician counseling. *Simple, concise advice from a clinician can yield cessation rates of 10–20%.* Additive strategies include more intensive counseling; nicotine replacement therapy with patches, gum, lozenges, or inhalers; and prescription medication with bupropion or varenicline (see Chapter 1).

For those Americans who do not use tobacco, the most modifiable cancer risk factors are nutrition and physical activity. *Prudent recommendations to reduce cancer risk are to (1) avoid tobacco; (2) be physically active; (3) maintain a healthy weight; (4) consume a diet rich in fruits, vegetables, and whole grains; (5) lower consumption of saturated and trans dietary fats; (6) limit alcohol use; and (7) avoid excess sun exposure.*

Another modifiable cancer risk factor is radiation from radiographic studies. Both standardization of CT radiation doses and limiting testing have been important steps in minimizing this risk.

Staging

The Tumor, Node, Metastasis (TNM) system is the commonly used classification to stage cancer. Staging is important not only because it correlates with the patient's long-term survival but also because it is used to determine treatment strategies.

Certain characteristics of cancers, not reflected in the TNM stage, may be used to indicate prognosis and guide treatment. Pathologic features seen on routine histologic examination for some cancers are very important; examples include the Gleason score for prostate cancer, HPV

Table 44–1. Estimated 10 most common cancer cases in the United States in males and females (all races).

	Males	Females
Rank	Total Cases [N] = 1,029,080	Total Cases [N] = 972,060
1	Prostate 299,010 (29)	Breast 310,720 (32)
2	Lung and bronchus 116,310 (11)	Lung and bronchus 118,270 (12)
3	Colon and rectum 81,540 (8)	Colon and rectum 71,270 (7)
4	Urinary bladder 63,070 (6)	Uterine corpus 67,880 (7)
5	Melanoma 59,170 (6)	Melanoma 41,470 (4)
6	Kidney and renal pelvis 52,380 (5)	Non-Hodgkin lymphoma 36,030 (4)
7	Non-Hodgkin lymphoma 44,590 (4)	Pancreas 31,910 (3)
8	Oral cavity and pharynx 41,510 (4)	Thyroid 31,520 (3)
9	Leukemia 36,450 (4)	Kidney and renal pelvis 29,230 (3)
10	Pancreas 34,530 (3)	Leukemia 26,320 (3)

Data from the American Cancer Society, 2024.

status of oropharyngeal cancer, and grade of sarcomas. Cancer specimens should also be sent for molecular diagnostic testing. Programmed death-ligand 1 (PD-L1) expression testing should be sent for certain cancers (including lung, head/neck, esophageal cancers).

Detterbeck FC et al. The proposed ninth edition TNM Classification of Lung Cancer. Chest. 2024;166:882. [PMID: 38885896]

Treatment

See Primary Cancer Treatment section below. Table 44–2 outlines treatment choices by cancer type for those responsive to systemic agents, and Tables 44–3, 44–4, 44–5, 44–6, 44–7, 44–8, and 44–9 provide lists of common chemotherapeutic agents.

TYPES OF CANCER

LUNG CANCER

BRONCHOGENIC CARCINOMA

ESSENTIALS OF DIAGNOSIS

- New cough or change in chronic cough.
- Dyspnea, hemoptysis, anorexia, weight loss.
- Enlarging lung nodule or mass; persistent opacity, atelectasis, or pleural effusion on chest radiograph or CT scan.
- Cytologic or histologic findings of lung cancer in sputum, pleural fluid, or biopsy specimen.

General Considerations

Lung cancer is the leading cause of cancer deaths in both men and women. The American Cancer Society (ACS) estimates 234,580 new diagnoses and 125,070 deaths from lung cancer in the United States in 2024, accounting for approximately 12% of new cancer diagnoses and 20% of all cancer deaths.

Cigarette smoking causes 85–90% of cases of lung cancer. Other environmental risk factors for the development of lung cancer include exposure to environmental tobacco smoke, radon, asbestos, diesel exhaust, ionizing radiation, metals (arsenic, chromium, nickel, iron oxide), and industrial carcinogens. A familial predisposition to lung cancer is recognized. Certain diseases are associated with an increased risk of lung cancer, including pulmonary fibrosis, COPD, and sarcoidosis.

The median age at diagnosis of lung cancer in the United States is 71 years; it is unusual under the age of 40 years. The combined relative 5-year survival rate for all stages of lung cancer is 27%.

There are five main histologic categories of bronchogenic carcinoma. **Squamous cell carcinomas** (29% of non–small-cell lung cancer [NSCLC] cases, based on US Surveillance, Epidemiology, and End Results National Program of Cancer Registries data, 2010–2017) arise from the bronchial epithelium and often present as intraluminal masses. They are usually centrally located and can present with hemoptysis. **Adenocarcinomas** (55% of NSCLC cases) arise from mucous glands or from any epithelial cell within or distal to the terminal bronchioles. They usually present as peripheral nodules or masses. **Adenocarcinomas in situ** (formerly **bronchioloalveolar cell carcinomas)** spread along preexisting alveolar structures (lepidic growth) without evidence of invasion. **Large cell carcinomas** (1.8% of cases) are a heterogeneous group of undifferentiated cancers that share large cells and do not fit into other categories. Large cell carcinomas are typically aggressive and have rapid doubling times. They present as central or peripheral masses. Cancers that are not better differentiated on pathologic review other than NSCLC or carcinomas not otherwise specified make up about 14% of cases. **Small cell carcinomas** (14% of all lung cancer cases) are tumors of bronchial origin that typically begin centrally, infiltrating submucosally to cause narrowing of the bronchus without a discrete luminal mass. They are aggressive cancers that often involve regional or distant metastasis on presentation.

For purposes of staging and treatment, bronchogenic carcinomas are divided into small-cell lung cancer (**SCLC**) and the other four types, labeled **NSCLC**. This practical classification reflects different natural histories and treatments. SCLC is prone to early hematogenous spread and has a more aggressive course with a median survival of 6–18 weeks if untreated.

Table 44–2. Treatment choices for cancers responsive to systemic agents (listed in alphabetical order by diagnosis).

Diagnosis	Initial Treatment
Acute lymphoblastic leukemia (ALL)	**Induction combination chemotherapy (Philadelphia chromosome–positive):** Cyclophosphamide, vincristine, doxorubicin/daunorubicin, dexamethasone (hyper-CVAD) alternating with cytarabine, methotrexate; add imatinib or dasatinib or nilotinib **Induction combination chemotherapy (Philadelphia chromosome–negative):** Daunorubicin, vincristine, prednisone, pegaspargase, cyclophosphamide; or hyper-CVAD alternating with methotrexate and cytarabine
Acute myeloid leukemia (AML)	**Induction combination therapy:** Cytarabine with daunorubicin or idarubicin, with gemtuzumab ozogamicin (CD33-positive), or with midostaurin or quizartinib (*FLT3*-mutated) Liposomal encapsulation of cytarabine and daunorubicin (therapy-related or myelodysplasia-related changes for ≥ 60 y) **Alternative therapy for intensive induction ineligible:** Azacitidine or decitabine with venetoclax; or Ivosidenib (*IDH1* mutation); or Enasidenib (*IDH2* mutation)
Anal cancer	Mitomycin with 5-fluorouracil or capecitabine with radiation (localized cancer) Carboplatin, paclitaxel with or without radiation therapy (metastatic cancer)
Bladder cancer	Gemcitabine, cisplatin followed by avelumab maintenance, or Methotrexate, vinblastine, doxorubicin, cisplatin (MVAC), or pembrolizumab and enfortumab vedotin-ejfv
Breast cancer	**Adjuvant hormone therapy:** *Premenopausal:* Tamoxifen *Postmenopausal:* Aromatase inhibitors (anastrozole, letrozole, exemestane) **Adjuvant therapy (*HER2* negative):** Doxorubicin, cyclophosphamide, followed by paclitaxel, or Docetaxel, cyclophosphamide, or Olaparib if germline *BRCA1/2* pathogenic variants, or High-risk triple-negative—preoperative pembrolizumab/carboplatin/paclitaxel, followed by pembrolizumab/cyclophosphamide/doxorubicin or epirubicin, followed by adjuvant pembrolizumab **Adjuvant therapy (*HER2* positive):** Docetaxel, carboplatin, trastuzumab with or without pertuzumab, or Paclitaxel, trastuzumab
Carcinoid	Octreotide LAR or lanreotide or everolimus or lutetium (Lu)-177 dotatate
Cervical cancer	**With radiation:** Cisplatin or carboplatin **Combination chemotherapy:** Cisplatin or carboplatin, paclitaxel, with or without bevacizumab, add pembrolizumab for PD-L1–positive tumors
Chronic lymphocytic leukemia (CLL)	Venetoclax with obinutuzumab, or acalabrutinib with or without obinutuzumab, or zanubrutinib
Chronic myeloid leukemia (CML)	Nilotinib or dasatinib or imatinib or bosutinib
Colon cancer	5-Fluorouracil, leucovorin, oxaliplatin (FOLFOX) with or without bevacizumab, or Capecitabine, oxaliplatin (CAPEOX) with or without bevacizumab, or 5-Fluorouracil, leucovorin, irinotecan (FOLFIRI) with or without bevacizumab 5-Fluorouracil, leucovorin, oxaliplatin, irinotecan (FOLFIRINOX) with or without bevacizumab Cetuximab or panitumumab added to CAPEOX, FOLFOX, or FOLFIRI for *KRAS/NRAS/BRAF* wild-type and left-sided cancers Capecitabine or 5-fluorouracil/leucovorin with or without bevacizumab Pembrolizumab, dostarlimab-gxly; or nivolumab with or without ipilimumab (deficient mismatch repair [dMMR]/high-level microsatellite instability [MSI-H])
Esophageal and esophagogastric junction cancer	Paclitaxel, carboplatin, oxaliplatin, 5-fluorouracil, or capecitabine with radiation, or 5-Fluorouracil, leucovorin, oxaliplatin, docetaxel (FLOT) (perioperative) Nivolumab and ipilimumab or pembrolizumab for neoadjuvant or perioperative (MSI-H/dMMR) 5- Fluorouracil or capecitabine, leucovorin, oxaliplatin, nivolumab, or pembrolizumab (HER2-negative unresectable, recurrent, or metastatic disease)
Head and neck cancer (non-nasopharyngeal)	Cisplatin with radiation therapy, or Carboplatin with 5-fluorouracil with radiation therapy, or Docetaxel, cisplatin, 5-fluorouracil (induction) Pembrolizumab (PD-L1 ≥ 1%), or Pembrolizumab/cisplatin or carboplatin/5-fluorouracil (recurrent, unresectable, or metastatic disease)

(*continued*)

Table 44–2. Treatment choices for cancers responsive to systemic agents (listed in alphabetical order by diagnosis). (continued)

Diagnosis	Initial Treatment
Hepatocellular cancer	Atezolizumab with bevacizumab Tremelimumab-actl with durvalumab
Hodgkin lymphoma	Doxorubicin, bleomycin, vinblastine, dacarbazine (ABVD), or Brentuximab vedotin (BV) or nivolumab with doxorubicin, vinblastine, dacarbazine, or BV, etoposide, cyclophosphamide, doxorubicin, dacarbazine, dexamethasone (BrECADD)
Kidney (renal cell) cancer	**Clear cell histology:** Axitinib or lenvatinib plus pembrolizumab, or ipilimumab plus nivolumab, or cabozantinib plus nivolumab **Non–clear cell histology:** Cabozantinib with or without nivolumab or lenvatinib with pembrolizumab
Melanoma	Neoadjuvant: Nivolumab with ipilimumab or pembrolizumab Adjuvant: Nivolumab, pembrolizumab, or dabrafenib/trametinib (*BRAF* mutation) Metastatic: Nivolumab with ipilimumab or relatlimab-rmbw Dabrafenib/trametinib, vemurafenib/cobimetinib, or encorafenib/binimetinib (*BRAF* mutation)
Mesothelioma	Cisplatin or carboplatin/pemetrexed with or without bevacizumab or pembrolizumab, or Nivolumab with ipilimumab
Multiple myeloma	**(Transplant candidates):** Bortezomib, dexamethasone, lenalidomide, daratumumab followed by autologous or mini-allogeneic stem cell transplantation **(Non-transplant candidates):** Bortezomib, lenalidomide, dexamethasone, or Daratumumab, lenalidomide, dexamethasone, or Isatuximab-irfc, bortezomib, lenalidomide, dexamethasone
Non-Hodgkin lymphoma (intermediate and high-grade)	Cyclophosphamide, doxorubicin, vincristine, prednisone, rituximab[1] (CHOP-R), or Polatuzumab vedotin-piiq, rituximab, cyclophosphamide, doxorubicin, prednisone, or Etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, rituximab[1] (dose-adjusted R-EPOCH) (for MYC and either BCL2 or BCL6 rearrangements)
Non-Hodgkin lymphoma (low-grade)	Bendamustine plus obinutuzumab or rituximab[1], or Cyclophosphamide, vincristine, doxorubicin, prednisone, obinutuzumab or rituximab[1], or Cyclophosphamide, vincristine, prednisone, with binutuzumab or rituximab[1], or Lenalidomide, rituximab[1]
Non–small cell lung cancer	**Neoadjuvant and adjuvant therapy:** Cisplatin, gemcitabine or docetaxel (squamous histology), or Cisplatin, pemetrexed (nonsquamous histology) Add nivolumab, pembrolizumab, or durvalumab to platinum-doublet chemotherapy if candidate for immune checkpoint inhibitor **Single-agent therapy for advanced or metastatic disease:** Erlotinib, gefitinib, osimertinib, afatinib, or dacomitinib (*EGFR* mutation positive) Sotorasib or adagrasib (*KRAS* G12C mutation positive) Alectinib, brigatinib, ceritinib, crizotinib, lorlatinib (*ALK* rearrangement) Ceritinib, crizotinib, entrectinib, or repotrectinib (*ROS1* rearrangement) Larotrectinib, entrectinib, or repotrectinib (*NTRK* gene fusion positive) Capmatinib, crizotinib, or tepotinib (*MET* amplification) Cabozantinib, selpercatinib, or pralsetinib (*RET* rearrangement positive) Pembrolizumab, or atezolizumab, or cemiplimab-rwlc (PD-L1 ≥ 50%) **Combination therapy for advanced or metastatic disease:** Carboplatin or cisplatin/pemetrexed/pembrolizumab (nonsquamous); carboplatin/paclitaxel or albumin-bound paclitaxel/pembrolizumab (squamous)
Ovarian cancer	Paclitaxel, carboplatin, with or without bevacizumab, or 5-Fluorouracil/leucovorin or capecitabine, oxaliplatin
Pancreatic cancer	**Combination chemotherapy:** Gemcitabine, albumin-bound paclitaxel, or 5-Fluorouracil, leucovorin, irinotecan, oxaliplatin (FOLFIRINOX), or Gemcitabine, capecitabine, or Gemcitabine, cisplatin (for *BRCA1/2* or *PALB2* mutation), or Liposomal irinotecan, 5-fluorouracil, leucovorin, oxaliplatin (NALIRIFOX) **Single-agent chemotherapy:** Gemcitabine or capecitabine
Prostate cancer	Androgen deprivation therapy (eg, leuprolide or degarelix with or without abiraterone, enzalutamide, apalutamide, or docetaxel)

(*continued*)

Table 44–2. Treatment choices for cancers responsive to systemic agents (listed in alphabetical order by diagnosis). (continued)

Diagnosis	Initial Treatment
Rectal cancer	5-Fluorouracil or capecitabine with radiation, or FOLFOX or CAPEOX
Small cell lung cancer	Cisplatin, etoposide with radiation followed by durvalumab (limited stage) Cisplatin or carboplatin, etoposide, plus atezolizumab or durvalumab (extensive stage)
Soft tissue sarcomas	**Combination chemotherapy:** Doxorubicin, dacarbazine (AD), or Doxorubicin, ifosfamide, mesna (AIM), or Ifosfamide, epirubicin, mesna **Single-agent therapy:** Imatinib or avapritinib (GI stromal tumors) Doxorubicin or epirubicin or liposomal doxorubicin
Stomach (gastric) cancer	5-Fluorouracil, leucovorin, oxaliplatin, docetaxel (FLOT) (perioperative) 5-Fluorouracil or capecitabine with oxaliplatin or cisplatin 5-Fluorouracil or capecitabine, oxaliplatin, nivolumab, or pembrolizumab Add trastuzumab for *HER2*-overexpressing adenocarcinomas
Testicular cancer	Cisplatin, etoposide (EP), or Bleomycin, etoposide, cisplatin (BEP), or Etoposide, mesna, ifosfamide, cisplatin (VIP)
Thyroid cancer	**Single-agent therapy:** Radioiodine (^{131}I) lenvatinib (papillary), vandetanib, or cabozantinib (medullary)
Uterine cancer	**Hormone therapy:** Progestins, tamoxifen, aromatase inhibitors **Chemotherapy:** Cisplatin with radiation Carboplatin, paclitaxel with or without pembrolizumab or dostarlimab-gxly Carboplatin, paclitaxel, trastuzumab (*HER2* positive)
Waldenström macroglobulinemia (a form of lymphoplasmacytic lymphoma)	**Plasmapheresis alone or followed by:** Ibrutinib with or without rituximab[1] Bendamustine, rituximab[1], or Zanubrutinib

[1] In patients with past hepatitis B virus (HBV) infection, rituximab should be used with anti-HBV agent (eg, entecavir) prophylaxis since HBV reactivation, fulminant hepatitis, and, rarely, death can occur otherwise.

Clinical Findings

Lung cancer is symptomatic at diagnosis in a majority of patients. The clinical presentation depends on the type and location of the primary tumor, the extent of local spread, and the presence of distant metastases and any paraneoplastic syndromes.

A. Symptoms and Signs

Anorexia, weight loss, or asthenia occurs in 55–90% of patients presenting with a new diagnosis of lung cancer. Up to 60% of patients have a new cough or a change in a chronic cough; 6–31% have hemoptysis; and 25–40% report pain, either nonspecific chest pain or pain from

Table 44–3. Common alkylating agents for cancer treatment (listed alphabetically within classes).

Agent	Usual Adult Dosage	Adverse Effects
Alkylating Agents—Nitrogen Mustards		
Cyclophosphamide (Cytoxan)	500–1000 mg/m^2 intravenously every 3 weeks; 100 mg/m^2/day orally for 14 days every 4 weeks; various doses	Acute: nausea and vomiting Delayed: myelosuppression, alopecia, hemorrhagic cystitis, cardiotoxicity (high dose)
Alkylating Agents—Platinum Analogs		
Cisplatin (Platinol)	50–100 mg/m^2 intravenously every 3–4 weeks; 20 mg/m^2/day intravenously for 5 days every 3 weeks; various doses	Acute: nausea and vomiting Delayed: nephrotoxicity, ototoxicity, neurotoxicity, myelosuppression, electrolyte disturbances

Table 44–4. Common antimetabolite agents for cancer treatment (listed alphabetically within classes).

Agent	Usual Adult Dosage	Adverse Effects
Antimetabolites—Folate Antagonists		
Pemetrexed (Alimta)	500 mg/m^2 intravenously every 3 weeks	Acute: nausea, vomiting, diarrhea, rash Delayed: myelosuppression, fatigue, mucositis
Antimetabolites—Pyrimidine Analogs		
Azacitidine (Vidaza)	75–100 mg/m^2 subcutaneously or intravenously for 7 days every 4 weeks	Acute: injection site reaction (subcutaneously), nausea, diarrhea, fever Delayed: myelosuppression, dyspnea, arthralgia
Capecitabine (Xeloda)	1000–1250 mg/m^2 orally twice a day for 14 days every 3 weeks	Acute: nausea, vomiting, diarrhea Delayed: hand-foot syndrome, mucositis, hyperbilirubinemia, myelosuppression
Fluorouracil (Adrucil)	400 mg/m^2 intravenous bolus followed by 2400 mg/m^2 intravenously over 46 hours every 2 weeks; 1000 mg/m^2 intravenously via continuous infusion for 4–5 days every 3–4 weeks; various doses	Acute: nausea, vomiting, diarrhea Delayed: myelosuppression, hand-foot syndrome, mucositis, photosensitivity, cardiotoxicity (rare)
Gemcitabine (Gemzar)	1000–1250 mg/m^2 intravenously on days 1 and 8 every 3 weeks or days 1, 8, 15 every 4 weeks; various doses	Acute: nausea, vomiting, rash, flu-like symptoms, fever, diarrhea Delayed: myelosuppression, edema, elevated transaminases

bony metastases to the vertebrae, ribs, or pelvis. Local spread may cause endobronchial obstruction with atelectasis and postobstructive pneumonia, pleural effusion (12–33%), change in voice (compromise of the recurrent laryngeal nerve), *superior vena cava syndrome* (obstruction of the superior vena cava with supraclavicular venous engorgement), and *Horner syndrome* (ipsilateral ptosis, miosis, and anhidrosis from involvement of the inferior cervical ganglion and the paravertebral sympathetic chain). Distant metastases to the liver are associated with asthenia and weight loss. Brain metastases (10% in NSCLC, more common in adenocarcinoma, and 20–30% in SCLC) may present with headache, nausea, vomiting, seizures, dizziness, or altered mental status.

Paraneoplastic syndromes are patterns of organ dysfunction related to immune-mediated or secretory effects of neoplasms. These syndromes occur in 10–20% of patients with lung cancer. In patients with small cell carcinoma, SIADH can develop in 10–15%; in those with squamous cell carcinoma, hypercalcemia can develop in 10%. Digital clubbing is seen in up to 20% of patients at diagnosis (see Figure 6–39). Other common paraneoplastic syndromes include increased ACTH production, anemia, hypercoagulability, peripheral neuropathy, and the Lambert-Eaton myasthenic syndrome.

B. Laboratory Findings

The diagnosis of lung cancer rests on examination of a tissue or cytology specimen. *Sputum cytology* is highly specific but insensitive; the yield is highest when there are lesions in the central airways. While the diagnostic yield of *CT-guided biopsy* of peripheral nodules approaches 80–90%, the rates of pneumothorax are significant (15–30%), especially in those with emphysema. *Thoracentesis* (sensitivity 50–65%) can be used to establish a diagnosis of lung cancer in patients with malignant pleural effusions. *Fine-needle aspiration (FNA)* of palpable supraclavicular or cervical lymph nodes is frequently diagnostic.

Fiberoptic bronchoscopy allows visualization of the major airways, cytology brushing of visible lesions or lavage of lung segments with cytologic evaluation of specimens, direct biopsy of endobronchial abnormalities, blind transbronchial biopsy of the pulmonary parenchyma or peripheral nodules, and FNA biopsy of mediastinal lymph nodes. *Electromagnetic navigational bronchoscopy* allows bronchoscopic approaches to small peripheral nodules. *Mediastinoscopy, video-assisted thoracoscopic surgery (VATS),* and *thoracotomy* may be necessary in cases where less invasive techniques fail to yield a diagnosis.

Table 44–5. Common antimicrotubules for cancer treatment (listed alphabetically within classes).

Agent	Usual Adult Dosage	Adverse Effects
Antimicrotubules—Vinca Alkaloids		
Vincristine (Oncovin)	0.5–1.4 mg/m^2 intravenously every 3 weeks; various doses; maximum single dose usually limited to 2 mg	Acute: constipation, nausea Delayed: peripheral neuropathy, alopecia
Antimicrotubules—Taxanes		
Paclitaxel (Taxol)	135–175 mg/m^2 intravenously every 3 weeks; 50–80 mg/m^2 intravenously weekly; various doses	Acute: diarrhea, nausea, vomiting, hypersensitivity Delayed: myelosuppression, peripheral neuropathy, alopecia, mucositis, arthralgia

Table 44–6. Common enzyme inhibitors for cancer treatment (listed alphabetically within classes).

Agent	Usual Adult Dosage	Adverse Effects
Enzyme Inhibitors—Anthracyclines		
Doxorubicin (Adriamycin)	45–75 mg/m^2 intravenously every 3 weeks; various doses	
Enzyme Inhibitors—Topoisomerase Inhibitors		
Etoposide (Vepesid)	50–100 mg/m^2 intravenously for 3–5 days every 3 weeks	Acute: nausea, vomiting, diarrhea, hypersensitivity, fever, hypotension Delayed: myelosuppression, alopecia, fatigue
Irinotecan (Camptosar)	180 mg/m^2 intravenously every other week; various doses	Acute: diarrhea, cholinergic syndrome, nausea, vomiting Delayed: myelosuppression, alopecia, asthenia

C. Imaging

Nearly all patients with lung cancer have abnormal findings on CXR or CT scan (Figure 44–1). These findings are rarely specific for a particular diagnosis. Interpretation of characteristic findings in isolated nodules is described in Chapter 9.

D. Special Examinations

1. Staging—Accurate staging is crucial (1) to provide the clinician with information to guide treatment, (2) to provide the patient with accurate information regarding prognosis, and (3) to standardize entry criteria for clinical trials to allow interpretation of results.

Staging of NSCLC uses two integrated systems and is continuously updated. The ninth edition of the *American Joint Committee on Cancer (AJCC)/Union for International Cancer Control (UICC)* stage classification for lung cancer became available in January 2025. The *AJCC TNM international staging system* attempts a physical description of the neoplasm: T describes the size and location of the primary tumor; N describes the presence and location of nodal metastases; and M refers to the presence or absence of distant metastases. These TNM stages are grouped into summary stages I–IV, and these are used to guide therapy (Table 44–10).

SCLC is traditionally divided into two categories: *limited disease* (30% of cases), when the tumor is limited to the unilateral hemithorax (including contralateral mediastinal nodes); or *extensive disease* (70% of cases), when the tumor extends beyond the hemithorax (including pleural effusion). It is also recommended to stage SCLC according to the TNM staging system (Table 44–10).

For both SCLC and NSCLC, a complete examination is essential to exclude obvious metastatic disease to lymph nodes, skin, and bone. A detailed history is essential because *the patient's performance status is a powerful predictor of disease course.* All patients should have measurement of a CBC, serum electrolytes, calcium, creatinine, liver biochemical tests, LD, and albumin.

NSCLC patients being considered for surgery require meticulous evaluation to identify those with resectable

Table 44–7. Common hormonal agents for cancer treatment (listed alphabetically within classes).

Agent	Usual Adult Dosage	Adverse Effects
Hormonal—Antiandrogens		
Enzalutamide (Xtandi)	160 mg orally once daily	Acute: asthenia, diarrhea Delayed: hot flashes, arthralgia, peripheral edema, seizure (rare)
Hormonal—Aromatase Inhibitors		
Anastrozole (Arimidex)	1 mg orally once daily	Acute: nausea Delayed: hot flashes, peripheral edema, asthenia, hypercholesterolemia, arthralgia/myalgia, osteoporosis
Hormonal—LHRH Analogs		
Leuprolide (Lupron Depot, Eligard)	1 month: 7.5 mg intramuscularly or subcutaneously every month 3 month: 22.5 mg intramuscularly or subcutaneously every 3 months 4 month: 30 mg intramuscularly or subcutaneously every 4 months 6 month: 45 mg intramuscularly or subcutaneously every 6 months	
Hormonal—Selective Estrogen Receptor Modulators		
Tamoxifen (Nolvadex)	20–40 mg orally once daily	Acute: none Delayed: hot flashes, vaginal discharge, menstrual irregularities, arthralgia

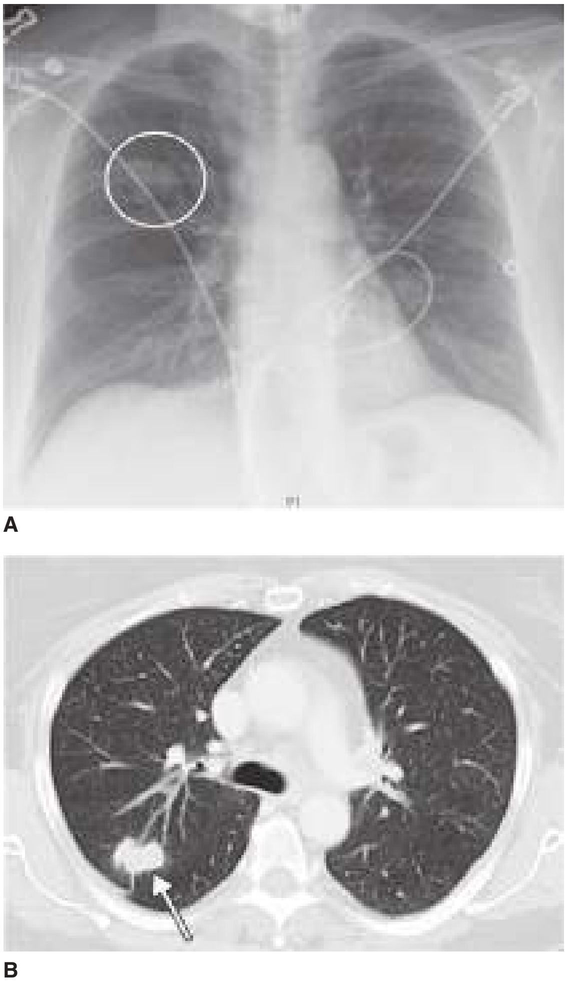
Table 44–8. Common targeted therapies in cancer treatment (listed alphabetically within classes).

Agent	Usual Adult Dosage	Adverse Effects
Targeted Therapy—Monoclonal Antibodies		
Bevacizumab (Avastin)	5–15 mg/kg intravenously every 2–3 weeks	Acute: infusion-related reaction Delayed: hypertension, proteinuria, wound healing complications, GI perforation, hemorrhage
Cetuximab (Erbitux)	Loading dose 400 mg/m^2 intravenously; maintenance dose 250 mg/m^2 intravenously weekly	Acute: infusion-related reaction, nausea, diarrhea Delayed: acneiform skin rash, hypomagnesemia, asthenia, paronychial inflammation, dyspnea
Daratumumab (Darzalex)	16 mg/kg intravenously weekly for weeks 1–8, every 2 weeks for weeks 9–24, and every 4 weeks from week 25 until disease progression	Acute: infusion-related reaction, nausea Delayed: myelosuppression, fatigue, upper respiratory tract infection
Ipilimumab (Yervoy)	1–10 mg/kg intravenously every 3 weeks for a total of four doses	Acute: infusion-related reaction Delayed: immune-related reactions, fatigue, diarrhea, nausea, pruritus
Nivolumab (Opdivo)	240 mg intravenously every 2 weeks or 480 mg every 4 weeks; various doses	Acute: infusion-related reaction, vomiting Delayed: immune-mediated reactions, fatigue, nausea, decreased appetite
Pembrolizumab (Keytruda)	200 mg intravenously every 3 weeks or 400 mg every 6 weeks	Acute: infusion-related reaction, nausea Delayed: immune-mediated reactions, fatigue, cough
Rituximab (Rituxan)	375 mg/m^2 intravenously weekly for 4 weeks, or every 3–4 weeks; various doses	Acute: infusion-related reaction, TLS Delayed: lymphopenia, asthenia, rash, potential hepatitis B reactivation
Trastuzumab (Herceptin)	Initial dose 4 mg/kg intravenously, then 2 mg/kg intravenously weekly; or initial dose 8 mg/kg, then 6 mg/kg, intravenously every 3 weeks	Acute: headache, nausea, diarrhea, infusion-related reaction Delayed: myelosuppression, pyrexia, cardiomyopathy, pulmonary toxicity (rare)
Targeted Therapy—Kinase Inhibitors		
Acalabrutinib (Calquence)	100 mg orally every 12 hours	Acute: diarrhea Delayed: myelosuppression, upper respiratory infection, musculoskeletal pain
Imatinib (Gleevec)	100–800 mg orally once daily with food; various doses	Acute: nausea, vomiting, diarrhea Delayed: edema, muscle cramps, rash, myelosuppression, hepatotoxicity
Osimertinib (Tagrisso)	80 mg orally once daily	Acute: diarrhea Delayed: myelosuppression, rash, dry skin, nail toxicity, cardiomyopathy (rare), prolonged QT interval (rare)

Table 44–9. Common miscellaneous agents used in cancer treatment (listed alphabetically).

Agent	Usual Adult Dosage	Adverse Effects
Miscellaneous Agents		
Abiraterone (Zytiga)	1000 mg orally once daily	Acute: diarrhea, edema Delayed: adrenal insufficiency, hepatotoxicity, joint pain, hypokalemia
Bortezomib (Velcade)	1.3 mg/m^2 intravenous bolus or subcutaneously on days 1, 4, 8, 11 followed by a 10-day rest, or weekly for 4 weeks followed by 13-day rest; various doses	Acute: nausea, vomiting, diarrhea Delayed: peripheral neuropathy, fatigue, myelosuppression
Lenalidomide (Revlimid)	5–25 mg orally once daily on days 1–21 of 28-day cycle; or continuously	Acute: diarrhea, rash Delayed: myelosuppression, fatigue, VTE, potential for birth defects

AUC, area under the curve; AV, atrioventricular; CPK, creatine phosphokinase; LHRH, LH-releasing hormone; MCV, mean corpuscular volume; TLS, tumor lysis syndrome.



▲ **Figure 44–1.** Squamous cell carcinoma of the right lung on CXR **(A)** and CT scan **(B).** (Reproduced, with permission, from Elsayes KM, Oldham SA. *Introduction to Diagnostic Radiology.* McGraw-Hill, 2014.)

disease. CT imaging is key for staging candidates for resection. The sensitivity and specificity of CT imaging for identifying lung cancer metastatic to the mediastinal lymph nodes are 57% (49–66%) and 82% (77–86%), respectively. Therefore, *chest CT imaging alone does not provide definitive staging information*. CT imaging helps determine where to biopsy and how the mediastinum should be sampled.

The combination of PET using 2-[^{18}F] fluoro-2-deoxyglucose (FDG-PET) and CT is an important modality for identifying metastatic foci in the mediastinum or distant sites. The sensitivity and specificity of FDG-PET/CT for detecting mediastinal spread of primary lung cancer depend on the size of mediastinal nodes or masses. When mediastinal lymph nodes smaller than 1 cm are present, the sensitivity and specificity of FDG-PET/CT for tumor involvement of nodes are 74% and 96%, respectively. When CT shows lymph nodes larger than 1 cm, the sensitivity and specificity are 95% and 76%, respectively.

Table 44–10. Five-year survival rates for non–small cell lung cancer, based on Tumor, Node, Metastasis (TNM) staging.

Stage	TNM Subset	5-Year Survival Rate for Clinical TNM	5-Year Survival Rate for Pathologic TNM
0	Carcinoma in situ		
1A1	T1aN0M0	92%	90%
1A2	T1bN0M0	83%	85%
IA3	T1cN0M0	77%	80%
IB	T2aN0M0	68%	73%
IIA	T2bN0M0	60%	65%
IIB	T1/T2, N1M0 T3N0M0	53%	56%
IIIA	T1/T2, N2M0 T3N1M0 T4, N0/N1, M0	36%	41%
IIIB	T1/T2, N3M0 T3/T4, N2M0	26%	24%
IIIC	T3/T4, N3M0	13%	12%
IVA	Any T, Any N, M1a/M1b	10%	—
IVB	Any T, Any N, M1c	0%	—

Reproduced with permission from Detterbeck FC et al. The Eighth Edition Lung Cancer Stage Classification. Chest. 2017;151(1):193–203 and data from Goldstraw P et al. The IASLC Lung Cancer Staging Project: proposals for revision of the TNM stage groupings in the forthcoming (eighth) edition of the TNM classification for lung cancer. J Thorac Oncol. 2015;11:39.

Obtaining an MRI of the brain is important to rule out brain metastases in all patients with SCLC and in patients with NSCLC with at least stage II disease or poorly differentiated histologies.

2. Preoperative assessment—See Chapter 3.

3. Pulmonary function testing—Many patients with NSCLC have moderate to severe chronic lung disease that increases the risk of perioperative complications as well as long-term pulmonary insufficiency following lung resection. *All patients considered for surgery require spirometry*. In the absence of other comorbidities, patients with good lung function (preoperative FEV_1 2 L or more) are at low risk for complications from lobectomy or pneumonectomy.

4. Screening—Screening with low-dose helical CT scans of the chest has been shown to improve lung cancer mortality rates. The National Lung Screening Trial, a multicenter randomized US trial involving over 53,000 current and former heavy smokers, showed that screening annually with low-dose helical CT for 3 years yielded a 20% relative reduction in lung cancer mortality and 6.7% reduction in all-cause mortality compared with chest radiography. Given these findings, US professional organizations have recommended annual screening with low-dose helical CT for lung cancer. The 2021 USPSTF recommendations specify *annual low-dose CT for smokers aged 50–80 years who have at least a 20 pack-year smoking history and who either currently smoke or have quit within the last 15 years*. Smoking cessation policies and efforts should be integrated with any screening program.

Treatment

A. Non–Small Cell Lung Carcinoma

Surgical resection offers the best chance for cure of NSCLC. Clinical features that preclude complete surgical resection include extrathoracic metastases or a malignant pleural effusion; or tumor involving the heart, pericardium, great vessels, esophagus, recurrent laryngeal or phrenic nerves, trachea, main carina, or contralateral mediastinal lymph nodes. Accordingly, stage I and stage II patients are treated with surgical resection where possible. Stage II and select cases of stage IB are additionally recommended to receive either neoadjuvant or adjuvant therapy. Stage IIIA patients have poor outcomes if treated with resection alone. They should undergo multimodality treatment that includes chemotherapy, immunotherapy, or radiotherapy. Inoperable stage IIIA and stage IIIB patients are treated with concurrent chemotherapy and radiation therapy followed by immunotherapy (checkpoint inhibitors) (Tables 44–2 and 44–8) and have improved survival. Stage IV patients are treated with systemic therapy (targeted therapy, chemotherapy, and/or immunotherapy) or symptom-based palliative therapy, or both.

Surgical approaches for early-stage cancers include lobectomy and sublobar resection. For patients who cannot tolerate lobectomy or have stage I primary tumors smaller than 2 cm, a sublobar resection (wedge resection or segmentectomy) may be considered. A phase 3 trial published in 2023 has shown that sublobar resection for patients with solitary primary tumors smaller than 2 cm achieves similar overall survival and disease-free survival compared to lobectomy.

Patients with clinical stage I primary NSCLC, who are not candidates for surgery because of significant comorbidity or other surgical contraindication, are candidates for *stereotactic body radiotherapy.* Stereotactic body radiotherapy, which is composed of multiple non-parallel radiation beams that converge, allows the delivery of a relatively large dose of radiation to a small, well-defined target.

Neoadjuvant therapy, in which antineoplastic medications are given in advance of surgery or radiation therapy, can also be considered. The Checkmate 816 and Keynote 671 trials showed that neoadjuvant treatment with a checkpoint inhibitor combined with chemotherapy prior to surgery for patients with early-stage NSCLC, leads to an improved event-free survival and pathologic complete response rates compared to neoadjuvant chemotherapy alone prior to surgery. Immune checkpoint inhibition (one form of immunotherapy) using programmed cell death 1 (PD-1) or programmed cell death–ligand 1 (PD-L1) inhibitors has an important role in the treatment of NSCLC (Tables 44–2 and 44–8). Checkpoint inhibitors release T cells from the inhibitory signals they receive from tumor cells via the PD-1 pathway, restoring antitumor immunity.

Adjuvant therapy consists of administering antineoplastic medications following surgery or radiation therapy. Cisplatin-containing regimens have shown an overall survival benefit in at least stage II disease and a subset of stage IB disease where primary tumor size exceeds 4 cm. Patients with epidermal growth factor receptor (*EGFR*) pathogenic variants (exon 19 del or L858R) and stage IB and higher are candidates for osimertinib to follow adjuvant chemotherapy per the ADAURA trial, which showed improved disease-free survival rates. Atezolizumab or pembrolizumab (checkpoint inhibitors) can be given for 1 year post–adjuvant chemotherapy to patients with resected stage IB to IIIA NSCLC, based on phase 3 trials showing improvement in disease-free survival compared with adjuvant chemotherapy without checkpoint inhibitor.

Patients with locally advanced disease (stages IIIA and IIIB) who are not surgical candidates have improved survival when treated with concurrent chemotherapy and radiation therapy followed by immunotherapy. The PACIFIC trial showed improved survival outcomes by adding durvalumab (PD-L1 inhibitor) as consolidation therapy post–definitive chemoradiation.

For stage IIIB and stage IV NSCLC, options for therapy include targeted therapy, cytotoxic chemotherapy, and immunotherapy. The approach to therapy is individualized based on molecular profiling and PD-L1 testing. Molecular profiling is offered as next-generation sequencing multigene assays. The key driver mutations in lung cancer include *EGFR, ALK, BRAF, ROS1, NTRK, MET, RET*, and *KRAS* pathogenic variants, but only a minority of all lung cancer cases harbor these mutations. Difficulties in testing may arise when only small fine-needle aspirate biopsies are obtained; to have sufficient tissue for analysis, it is recommended that clinicians obtain core biopsies. PD-L1 expression is a flawed but actively used biomarker to predict response to checkpoint inhibitor therapy (specifically, PD-1 and PD-L1 inhibitors).

Targeted therapy plays a pivotal role in NSCLC (Tables 44–2 and 44–8). Activating *EGFR* pathogenic variants are found in approximately 10–20% of the White population and 30–48% of the Asian population and are usually found among nonsmokers to light smokers, women, and persons with nonsquamous histologies (particularly adenocarcinomas). For patients with sensitizing *EGFR* variants, osimertinib (a third-generation EGFR tyrosine kinase inhibitor) with or without chemotherapy is recommended as first-line treatment. Response rates with third-generation EGFR tyrosine kinase inhibitors in patients with *EGFR* variants are at least 70%, and median overall survival is estimated to be 21–33 months. Amivantamab (an EGFR-MET bispecific antibody) with lazertininb (another third-generation EGFR tyrosine kinase inhibitor) is another FDA-approved option for first-line treatment for patients with sensitizing *EGFR* variants.

Approximately 5% of all patients with NSCLC carry translocations of *ALK* resulting in novel fusion gene products with oncogenic activity. For patients with *ALK*-rearranged lung cancers, ALK tyrosine kinase inhibitors are recommended therapeutic agents. Alectinib, brigatinib, and lorlatinib are recommended as first-line agents in *ALK*-rearranged lung cancer, with response rates ranging from 74–83%. Approximately 1–2% of NSCLC harbor *ROS1* rearrangements, and they are usually lung adenocarcinomas found among nonsmokers or light smokers. *ROS1*-rearranged lung cancers respond to crizotinib (*ALK*, *cMET*, and *ROS1* tyrosine kinase inhibitor) and entrectinib (multikinase inhibitor, including ROS-1), with response rates > 70%. MET exon 14 (METex14) skipping mutations are found in 3% of lung adenocarcinomas. Capmatinib or tepotinib (MET inhibitors) is recommended as first-line treatment for patients with METex14 skipping mutation. *BRAF* mutations have been found in 2% of NSCLC patients and first-line treatment includes the combination of dabrafenib (BRAF inhibitor) and trametinib (MEK inhibitor). This combination shows response rates > 60% in patients with *BRAF V600E* pathogenic variants. Treatment with larotrectinib (TRKA/B/C inhibitor) or entrectinib (multikinase inhibitor, including TRKA/B/C) is recommended for patients whose tumors reveal NTRK 1/2/3 gene fusion. Selpercatinib and pralsetinib (RET inhibitors) are recommended first-line treatments for RET fusion–positive NSCLC. Finally, *KRAS* pathogenic variants are found among 30% of patients with adenocarcinomas, are associated with smoking, and have a poor prognosis. Sotorasib and adagrasib (*KRAS* G12C inhibitors) are FDA-approved for treating *KRAS* G12C mutated lung cancers after progression on first-line treatment.

For patients with stage IV NSCLC, with no targetable pathogenic gene variants and regardless of PD-L1 status, phase 3 trials have shown improved survival outcomes with adding a checkpoint inhibitor to platinum-doublet chemotherapy as first-line therapy (Table 44–2). One-year survival for pembrolizumab with platinum-doublet chemotherapy was 69% compared with 49% with chemotherapy alone. For patients with metastatic NSCLC with tumors expressing PD-L1 ≥ 50%, PD-1 checkpoint inhibitors can be given alone or combined with chemotherapy. Significant side effects and toxicity, especially with combination immunotherapy, have been reported with checkpoint inhibitors, specifically autoimmune manifestations such as hepatitis, thyroiditis, hypophysitis, colitis, pneumonitis, and type 1 diabetes mellitus. Treatment with chemotherapy, immunotherapy, or both in the setting of stage IV NSCLC is not curative but can prolong survival and is palliative in intent, leading to improved quality of life and symptom control.

B. Small Cell Lung Carcinoma

Response rates of SCLC to chemotherapy (Table 44–2) are excellent with 80–90% response in limited-stage disease (50–60% complete response), and 60–80% response in extensive-stage disease (15–20% complete response). However, remissions tend to be short-lived with a median duration of 6–8 months. Once the disease has recurred, median survival is 3–4 months. Overall, 2-year survival is 20–40% in limited-stage disease and 5% in extensive-stage disease (Table 44–11). Modest improvement in survival has been achieved with the addition of a checkpoint inhibitor (atezolizumab or durvalumab) to cisplatin or carboplatin and etoposide therapy in extensive-stage disease. In limited SCLC, thoracic radiation therapy is given *concurrently* with chemotherapy, and adjuvant immunotherapy with durvalumab (PD-L1 inhibitor) for 2 years post-chemoradiation is recommended and improves survival outcomes. There is a high rate of brain metastasis in patients with SCLC, even following a good response to chemotherapy.

Table 44–11. Median survival for small-cell lung carcinoma following treatment.

Stage	Mean 2-Year Survival	Median Survival
Limited	20–40%	15–20 months
Extensive	5%	8–13 months

Data from multiple sources, including Van Meerbeeck JP et al. Small-cell lung cancer. Lancet. 2011;378:1741 and Blackhall F et al. Treatment patterns and outcomes among patients with small-cell lung cancer in Europe: a retrospective study. BMJ Open. 2023;13(2):e052556.

C. Palliative Therapy

Photoresection with the Nd:YAG laser is sometimes performed on central tumors to relieve endobronchial obstruction, improve dyspnea, and control hemoptysis. External beam radiation therapy is also used to control dyspnea, hemoptysis, endobronchial obstruction, pain from bony metastases, obstruction from superior vena cava syndrome, and symptomatic brain metastases. Resection of a solitary brain metastasis improves quality of life and survival when combined with radiation therapy if there is no evidence of other metastatic disease. Stereotactic radiation therapy is offered for limited brain metastases. Repeated thoracenteses, pleurodesis, and PleurX catheter tube placement are key interventions for palliation of symptomatic malignant pleural effusions. Pain is very common in advanced disease. Meticulous efforts at pain control are essential (see Chapter 5). In addition to standard oncologic care, early referral to specialty palliative care is recommended in advanced disease to aid in pain and other symptom management. Such palliative care can modestly improve survival.

Prognosis

The overall 5-year survival rate for lung cancer is approximately 27%. Predictors of survival include the tumor type (SCLC versus NSCLC), molecular profiling, and stage, and the patient's performance status and weight loss in the prior 6 months. *Patients with targetable mutations have better overall survival when compared with those without mutations due to superior efficacy of targeted drug therapy.*

When to Refer

- With abnormal chest imaging suspicious for cancer, refer to a pulmonologist, a thoracic surgeon, or both for further diagnostic steps, staging, and/or treatment.
- Once a diagnosis of lung cancer is established, also refer to an oncologist, a radiation oncologist, or both for treatment options, depending on stage.
- Locally extensive, regionally advanced, and metastatic disease often require multimodal treatment strategies.

When to Admit

- Hypoxemia, respiratory distress, or hemoptysis.
- Severe pain or new neurologic symptoms concerning for brain or spinal metastasis.
- For surgery or other interventions.

PULMONARY METASTASIS

Pulmonary metastasis results from the spread of an extrapulmonary malignant tumor through vascular or lymphatic channels or by direct extension. Metastases usually occur via the pulmonary artery and typically present as multiple nodules or masses on chest radiography. The radiographic differential diagnosis of multiple pulmonary nodules also includes pulmonary arteriovenous malformation, infections, sarcoidosis, rheumatoid nodules, and granulomatosis with polyangiitis. Metastases to the lungs are found in 20–55% of patients with various metastatic malignancies. Carcinomas of the kidney, breast, rectum, colon, cervix, and malignant melanoma are the most likely primary tumors.

Lymphangitic carcinomatosis denotes diffuse involvement of the pulmonary lymphatic network by primary or metastatic lung cancer, probably a result of extension of tumor from lung capillaries to the lymphatics. **Tumor embolization** from extrapulmonary cancer (renal cell carcinoma, HCC, choriocarcinoma) is an uncommon route for tumor spread to the lungs. Metastatic cancer may also present as a **malignant pleural effusion**.

Clinical Findings

A. Symptoms and Signs

Symptoms are uncommon but include cough, hemoptysis and, in advanced cases, dyspnea and hypoxemia. Symptoms are more often referable to the site of the primary tumor.

B. Laboratory Findings

The diagnosis of metastatic cancer involving the lungs is usually established by identifying a primary tumor. Appropriate studies should be ordered if there is a suspicion of any primary cancer, such as breast, thyroid, testis, colorectal, or prostate. If the history, physical examination, and initial studies fail to reveal the site of the primary tumor, attention is better focused on the lung, where tissue samples obtained by bronchoscopy, percutaneous needle biopsy, VATS, or thoracotomy may establish the histologic diagnosis and suggest the most likely primary cancer. Occasionally, cytologic studies of pleural fluid or pleural biopsy reveals the diagnosis.

C. Imaging

Chest radiographs usually show multiple spherical densities with sharp margins. The lesions are usually bilateral, pleural, or subpleural in location, and more common in lower lung zones. Lymphangitic spread and solitary pulmonary nodule are less common radiographic presentations of pulmonary metastasis. CT imaging of the chest, abdomen, and pelvis may reveal the site of a primary tumor and will help determine feasibility of surgical resection of the metastatic lung tumors. FDG-PET/CT scan is helpful in identifying the site of a primary cancer and identifying other areas of extrathoracic metastasis.

Treatment

Once the diagnosis has been established, management consists of treatment of the primary neoplasm, usually with systemic treatments, and treatment of any pulmonary complications. Surgical resection of a *solitary* pulmonary nodule (**metastasectomy**) can be considered in the patient with known current or previous extrapulmonary cancer. Local resection of one or more pulmonary metastases is feasible in a few carefully selected patients with various sarcomas and carcinomas (ie, testis, colorectal, and kidney). *About 15–25% of metastatic solid tumor patients have metastases limited to the lungs and are surgical candidates.* Unfavorable prognostic factors also include shorter disease-free interval from primary tumor treatment to presentation of metastases and a larger number of metastases. However, to date, there have been no randomized data confirming the benefit of metastasectomy for pulmonary metastasis. For patients with unresectable disease or primary neoplasms for which pulmonary metastasectomy should not be considered, systemic treatment tailored to the primary tumor can be offered. Diligent attention to palliative care is essential (see Chapter 5).

MESOTHELIOMA

ESSENTIALS OF DIAGNOSIS

- Unilateral, nonpleuritic chest pain and dyspnea.
- Distant (> 20 years earlier) history of exposure to asbestos.
- Pleural effusion or pleural thickening or both on CXR.
- Malignant cells in pleural fluid or tissue biopsy.

General Considerations

Mesotheliomas are primary tumors arising from the surface lining of the pleura (80% of cases) or peritoneum (20% of cases). *Numerous studies have confirmed the association of malignant pleural mesothelioma with exposure to asbestos*. The lifetime risk to asbestos workers of developing malignant pleural mesothelioma is as high as 10%. The latent period between exposure and onset of symptoms ranges from 20 to 40 years. The clinician should inquire about asbestos exposure through mining, milling, manufacturing, shipyard work, insulation, brake linings, building construction and demolition, roofing materials, and other asbestos products (pipes, textiles, paints, tiles, gaskets, panels).

Clinical Findings

A. Symptoms and Signs

The average interval between onset of symptoms and diagnosis is 2–3 months; the median age at diagnosis is 72–74 years in Western countries. Symptoms include the insidious onset of shortness of breath, nonpleuritic chest pain, and weight loss. Physical findings include dullness to percussion, diminished breath sounds and, in some cases, digital clubbing.

B. Laboratory Findings

Pleural fluid is exudative and often hemorrhagic. Cytologic tests of pleural fluid are often negative. *VATS biopsy is usually necessary to obtain an adequate specimen for histologic diagnosis*. The histologic variants of malignant pleural mesothelioma are epithelial (50–60%), sarcomatoid (10%), and biphasic (30–40%). Since distinction from benign inflammatory conditions and metastatic adenocarcinoma may be difficult, immunohistochemical stains are important to confirm the diagnosis.

C. Imaging

Radiographic abnormalities consist of nodular, irregular, unilateral pleural thickening and varying degrees of unilateral pleural effusion. Sixty percent of patients have right-sided disease, while only 5% have bilateral involvement. CT scans demonstrate the extent of pleural involvement. PET-CT is used to help differentiate benign from malignant pleural disease, improve staging accuracy, and identify candidates for aggressive surgical approaches.

Complications

Malignant pleural mesothelioma progresses rapidly as the tumor spreads along the pleural surface to involve the pericardium, mediastinum, and contralateral pleura. The tumor may eventually extend beyond the thorax to involve abdominal lymph nodes and organs. Progressive pain and dyspnea are characteristic. Local invasion of thoracic structures may cause superior vena cava syndrome, hoarseness, Horner syndrome, arrhythmias, and dysphagia.

Treatment

Chemotherapy and immunotherapy are the mainstay of treatment for pleural mesothelioma (Tables 44–2 and 44–8). Randomized trials have not shown a survival benefit for surgery, but these studies have limitations. Large-volume centers continue to consider surgery only for localized disease that is amenable to complete macroscopic surgical resection in a multimodal approach. For localized disease, surgical options include pleurectomy and decortication (surgical stripping of the pleura and pericardium from apex of the lung to diaphragm) or extrapleural pneumonectomy (a radical surgical procedure involving removal of the ipsilateral lung, parietal and visceral pleura, pericardium, and most of the hemidiaphragm). Surgical cytoreduction alone is not sufficient, and chemotherapy, radiation therapy, or both are included in a multimodality approach. In advanced unresectable disease, nivolumab and ipilimumab (checkpoint inhibitor therapy) or platinum therapy with pemetrexed can be offered first-line, with overall median survival rates ranging from 12–18 months in clinical trials.

Drainage of pleural effusions, pleurodesis, radiation therapy, and even surgical resection may offer palliative benefit to some patients.

Prognosis

Most patients die of respiratory failure and complications of local extension. Median survival time from diagnosis is 7–18 months. Five-year survival is 5–12%. Tumors that are predominantly sarcomatoid are more resistant to therapy and have a worse prognosis, with median survivals < 1 year. Poor prognostic features include poor performance status, non-epithelioid histology, male sex, nodal involvement, elevated LD, high WBC, low hemoglobin, and high platelet count.

When to Refer

Upon diagnosis, refer to a pulmonologist, oncologist, or possibly a thoracic surgeon who can evaluate the patient for multidisciplinary treatment.

When to Admit

- For pleural fluid drainage (thoracenteses, placement of an indwelling drainage catheter).
- For severe dyspnea.

HEPATOBILIARY CANCERS

HEPATOCELLULAR CARCINOMA

ESSENTIALS OF DIAGNOSIS

- Usually a complication of cirrhosis.
- Characteristic CT and MRI features may obviate the need for a confirmatory biopsy.

General Considerations

Malignant neoplasms of the liver that arise from parenchymal cells are called **HCCs** (accounting for 85% of liver cancers); those that originate in the ductular cells are called **cholangiocarcinomas** (15% or less). Uncommon tumors of the liver include mucinous cystic neoplasms of the liver (including biliary cystadenocarcinoma), angiosarcoma, lymphoma, and combined HCC-cholangiocarcinoma.

Worldwide, HCCs are the third most common cause of cancer-related deaths and the sixth most common in incidence. They are *associated with cirrhosis in 85% of cases.* The risk of HCC developing in a patient with cirrhosis is 3–5% a year. In Africa and most of Asia, *hepatitis B virus (HBV) infection* (including "occult" HBV infection; see Chapter 18) is a major etiologic factor, and a family history of HCC increases the risk synergistically. In the United States and other Western countries, cirrhosis caused by alcohol and *metabolic dysfunction-associated steatotic liver disease (MASLD)* has become the predominant cause. Incidence rates rose more than twofold after 1978, with a decrease in 35- to 49-year-olds after 2006 and in 55- to 64-year-olds after 2015 in White, Latina/Latino, and Asian/Pacific Islander persons and subsequently in Black, American Indian, and Alaskan native persons. Nevertheless, mortality rates have continued to increase in those over 65 years old. In Western countries, risk factors for HCC in patients known to have cirrhosis are male sex, age > 55 years (although there has been an increase in the number of younger cases), Latino/Latina or Asian ethnicity, family history in a first-degree relative, overweight, obesity (especially in early adulthood), alcohol use (especially in combination with obesity), tobacco use, diabetes mellitus, hypothyroidism (in women), a prolonged prothrombin time, a low platelet count, and an elevated serum transferrin saturation. The risk of HCC is higher in persons with a viral rather than nonviral cause of cirrhosis and may be lowest in persons with autoimmune diseases. Other associations include high levels of HBV replication, high hepatitis B surface antigen levels, HBV genotype C, hepatitis D coinfection, elevated serum ALT and bilirubin and low serum albumin levels, and increased liver stiffness in persons with chronic hepatitis B (in whom antiviral therapy to suppress HBV replication reduces the risk); hemochromatosis; aflatoxin exposure; α-1-antitrypsin deficiency; tyrosinemia; and radiation exposure. *In patients with the metabolic syndrome and MASLD, HCC may rarely arise from steatohepatitis in the absence of cirrhosis.* Hepatocellular adenoma may be a precursor to HCC (see Chapter 18).

The fibrolamellar variant of HCC generally occurs in young women with a second smaller peak in older persons; it is characterized by a distinctive histologic picture, absence of risk factors, unique genomic profiles, and an indolent course. Vinyl chloride exposure is associated with angiosarcoma of the liver.

Clinical Findings

A. Symptoms and Signs

The presence of HCC may be unsuspected until there is deterioration in the condition of a cirrhotic patient who was formerly stable. Cachexia, weakness, and weight loss are associated symptoms. The sudden appearance of ascites, which may be bloody, suggests *portal or hepatic vein thrombosis* by cancer or bleeding from a necrotic cancer.

Physical examination may show tender enlargement of the liver, occasionally with a palpable mass. In Africa, the typical presentation in young patients is a rapidly expanding abdominal mass. Auscultation may reveal a bruit over the tumor or a friction rub when the tumor has extended to the surface of the liver.

B. Laboratory Findings

Laboratory tests may reveal leukocytosis, as opposed to the leukopenia that is frequently encountered in cirrhotic patients. Anemia is common, but a normal or elevated hematocrit value may be found in up to one-third of patients owing to elaboration of erythropoietin by the tumor. Serum *α-fetoprotein (AFP)* levels are elevated in up to 70% of patients with HCC in Western countries; however, mild elevations (10–200 ng/mL [10–200 mcg/L]) are also often seen in patients with chronic hepatitis. Serum levels of *des-γ-carboxy prothrombin* are elevated in up to 90% of patients with HCC, but they may also be elevated in patients with vitamin K deficiency, chronic hepatitis, and metastatic cancer.

C. Imaging

Multiphasic helical CT and MRI with contrast enhancement are the preferred imaging studies for determining the location and vascularity of the tumor; MRI may be more sensitive than CT, and imaging with gadoxetic acid increases sensitivity. Lesions smaller than 1 cm may be difficult to characterize. Based on stringent criteria developed by the American College of Radiology through its Liver Imaging Reporting and Data System (LI-RADS), the Organ Procurement and Transplantation Network, and the American Association for the Study of Liver Diseases, arterial phase enhancement of *a lesion that is ≥ 1 cm in diameter followed by delayed hypointensity ("washout") (LI-RADS 5) has a 93% specificity, though only a 67% sensitivity, for HCC.*

Abbreviated MRI—shorter sequences of during the arterial phase of contrast—has shown promise in trials in Asia and is being explored in a large multicenter trial in the United States. PET may improve detection of extrahepatic metastases.

D. Liver Biopsy and Staging

Liver biopsy is diagnostic, although seeding of the needle tract by cancer is a potential risk (1–3%). For lesions smaller than 1 cm, ultrasonography may be repeated every 3 months followed by further investigation of enlarging lesions. For lesions 1 cm or larger, biopsy can be deferred when characteristic arterial hypervascularity and delayed washout are demonstrated on either multiphasic helical CT or MRI with contrast enhancement in a patient with cirrhosis or if surgical resection is planned.

The TNM system is the commonly used classification to stage HCC. Staging is important not only because it correlates with the patient's long-term survival but also because it is used to determine which patients should receive adjuvant or neoadjuvant therapy. The *Barcelona Clinic Liver Cancer (BCLC) staging system* is the preferred staging system and includes the *Child-Pugh class, Model for End-stage Liver Disease (MELD) score*, a score based on albumin and bilirubin (ALBI), tumor stage, and AFP and has the advantage of linking overall stage with preferred treatment modalities and with an estimation of life expectancy.

Screening & Prevention

Screening for the development of HCC is recommended in patients with chronic hepatitis B (beginning as early as age 20 years in persons of African descent, age 40 years in Asian men or Asian persons with a family history of HCC, and age 50 years in persons of other ethnicities) or cirrhosis caused by hepatitis C virus (HCV), HBV, or alcohol. There is some evidence that screening for HCC leads to a survival advantage over clinical diagnosis, but only a minority of cases are detected by screening. The standard screening approach is performing ultrasonography and obtaining serum AFP level every 6 months, although AFP testing has low sensitivity. A serum AFP level of ≥ 20 ng/mL (20 mcg/L) is generally the cutoff value that should trigger further evaluation by imaging.

Ultrasonography is less sensitive and more operator-dependent but is used to screen for hepatic nodules in high-risk patients. The sensitivity of ultrasonography alone for detecting early HCC is only 63%. Among patients with cirrhosis, 25% of nodules < 2 cm in diameter detected on a screening ultrasonography prove to be HCC. Patients with cancers detected by surveillance have a less advanced stage on average and greater likelihood that treatment will prolong survival than those whose cancers were not detected by surveillance. However, controversy persists about whether surveillance reduces cancer-related mortality.

CT and MRI are considered too expensive for routine screening; however, "abbreviated" MRI in which the number of sequences acquired is limited is under study as a time- and cost-effective screening approach.

Treatment

If liver function is preserved (Child-Pugh class A or possibly B) and portal vein thrombosis is not present, surgical resection of a solitary HCC may result in cure. Laparoscopic and robotic liver resection has been performed in selected cases.

Liver transplantation may be appropriate for some patients with advanced cirrhosis, with reported 5-year survival rates of up to 75%. The recurrence-free survival may be better for liver transplantation than for resection in patients with well-compensated cirrhosis and small tumors (one tumor < 5 cm or three or fewer tumors each < 3 cm in diameter [*Milan criteria*]) and in those with expanded *University of California, San Francisco criteria* of one tumor ≤ 6.5 cm or three or fewer tumors ≤ 4.5 cm (or a combined tumor diameter of 8.5 cm) without vascular invasion. The *Extended Toronto criteria* include tumor differentiation, cancer-related symptoms, confinement of tumor to the liver, and absence of vascular invasion, without regard to tumor number or size, to determine candidacy for liver transplantation and appear to predict outcomes as well as the Milan criteria. After 6 months on the waiting list, patients with stage 2 HCC meeting the Milan criteria are awarded a fixed score of 3 points lower than the median MELD score for patients transplanted at the center where the candidate is listed (see Chapter 18), thereby increasing their chances of undergoing transplantation. However, orthotopic liver transplantation is often impractical because of the donor organ shortage, so living donor liver transplantation may be considered in these cases. Patients with larger tumors (3–5 cm), a serum AFP level of 1000 ng/mL (1000 mcg/L) or higher, or a MELD score of 20 or higher have poor posttransplantation survival. In patients with a serum AFP level > 1000 ng/mL (1000 mcg/L), downstaging by locoregional therapy to an AFP level < 500 ng/mL (500 mcg/L) improves survival following subsequent liver transplantation.

Treatment decisions are made based on tumor size, location, underlying liver function, and shared decision-making. Microwave ablation, radiofrequency ablation, cryotherapy, proton beam radiotherapy, or injection of absolute ethanol into tumors < 3 cm may prolong survival in patients who are not candidates for resection and have tumors that are accessible; these interventions, as well as stereotactic body radiation therapy (SBRT), may also provide a "bridge" to liver transplantation. *Microwave ablation* has become the preferred approach because it allows for shorter treatment time. **Transarterial chemoembolization (TACE)** and **transarterial radioembolization (TARE)** via the hepatic artery may also prolong survival in patients with a large or multifocal tumor in the absence of extrahepatic spread. SBRT is also being used to treat unresectable HCC and may be effective in treating lesions larger than those treated with ablation techniques.

The combination of atezolizumab, an immune checkpoint inhibitor, and bevacizumab, an antibody to the VEGF receptor, is the preferred first-line therapy for advanced HCC and has been shown to be superior to sorafenib (an oral multikinase inhibitor of Raf kinase, the VEGF receptor, and the platelet-derived growth factor receptor [and others]) that had been shown to prolong median survival as well as the time to radiologic progression by 3 months and had been the standard of care in these patients. The combination of immune checkpoint inhibitors tremelimumab and durvalumab was approved in 2022 as an alternative first-line (and second-line) therapy and may be preferable to atezolizumab and bevacizumab if large or bleeding esophageal varices are present. Lenvatinib is another oral multikinase inhibitor that was previously approved by the FDA for the same indications as sorafenib and achieves similar outcomes to atezolizumab and bevacizumab in real-world patients. Regorafenib is an oral multikinase inhibitor that provides a survival benefit for patients whose disease progresses despite sorafenib therapy, and nivolumab and pembrolizumab are immune checkpoint inhibitors that have been approved for advanced HCC. The combination of nivolumab and ipilimumab has been recommended as second-line therapy after failure of sorafenib. Cabozantinib, another multikinase inhibitor, has been approved by the FDA for the treatment of HCC after prior treatment with sorafenib, as has ramucirumab, an antibody to the VEGF receptor, which is approved for patients with an AFP level ≥ 400 ng/mL (400 mcg/L) and previous treatment with sorafenib. The *modified Response Evaluation Criteria in Solid Tumors* are used to assess treatment response based on tumor shrinkage and viability after locoregional and antiangiogenic treatment. Meticulous efforts at palliative care are essential for patients in whom disease progresses despite treatment or in whom advanced tumors, vascular invasion, or extrahepatic spread are present. Severe pain may develop in such patients due to expansion of the liver capsule by the tumor and requires concerted efforts at pain management, including the use of opioids (see Chapter 5).

Prognosis

In the United States, overall 1- and 5-year survival rates for patients with HCC are 23% and 5%, respectively. Five-year survival rates rise to 56% (and over 70% in those eligible for liver transplantation) for patients with localized resectable disease (T1, T2, selected T3 and T4; N0; M0) but are virtually nil for those with locally unresectable or advanced disease. In patients with HCV-related HCC, the serum AFP level at the time of diagnosis of cancer has been reported to be an independent predictor of mortality. A serum AFP level ≥ 200 ng/mL (200 mcg/L) or increases of > 15 ng/mL/month predict worse outcomes in patients awaiting liver transplantation. In patients who are not eligible for surgery, cachexia and an elevated serum CRP level are associated with reduced survival. The fibrolamellar variant has been reported to have a higher recurrence rate but better survival than conventional HCC.

When to Refer

All patients with HCC should be referred to a specialist.

When to Admit

- Complications of cirrhosis.
- Severe pain.
- For surgery and other interventions.

CARCINOMA OF THE BILIARY TRACT

ESSENTIALS OF DIAGNOSIS

- Presents with obstructive jaundice, usually painless, often with dilated biliary tract.
- Pain is more common in gallbladder carcinoma than cholangiocarcinoma.
- A dilated gallbladder may be palpable (Courvoisier sign).
- Diagnosis by cholangiography with biopsy and brushings for cytology.

General Considerations

Carcinoma of the gallbladder occurs in approximately 2% of all people operated on for biliary tract disease; the incidence, like that of carcinoma of the bile ducts, had been decreasing in the United States but may be increasing again in some Western countries because of lifestyle changes. The onset is notoriously insidious, and the diagnosis is often made unexpectedly at surgery. *Cholelithiasis (often large, symptomatic stones) is usually present.* Other risk factors are chronic infection of the gallbladder with *Salmonella typhi*, adenomatous gallbladder polyps over 1 cm in diameter (particularly with hypoechoic foci on endoscopic ultrasound), mucosal calcification of the gallbladder (*porcelain gallbladder*), anomalous pancreaticobiliary ductal junction, high parity in women, oral menopausal hormone therapy, increased BMI, and aflatoxin exposure. Spread of the cancer—by direct extension into the liver or to the peritoneal surface—may be seen on initial presentation.

Carcinoma of the bile ducts (cholangiocarcinoma) accounts for 10–15% of all hepatobiliary malignancies and 3% of all cancer deaths in the United States. It is more prevalent in persons aged 50–70 years, with a slight male predominance, and more common in Asia. About 50% arise at the confluence of the hepatic ducts (*perihilar*, or so-called *Klatskin tumors*), and 40% arise in the *distal extrahepatic bile duct* (the incidence of which has risen since 1990); the remainder are *intrahepatic* (the incidence of which rose dramatically from the 1970s to the early 2000s and has continued to increase). Mortality from intrahepatic cholangiocarcinoma has been increasing at a higher rate than that for extrahepatic cholangiocarcinoma. The frequency of carcinoma in persons with a choledochal cyst has been reported to be over 14% at

20 years, and surgical excision is recommended. Most cases of cholangiocarcinoma are sporadic. There is an increased incidence of cholangiocarcinoma in patients with bile duct adenoma; Caroli disease; a biliary-enteric anastomosis; ulcerative colitis, especially those with primary sclerosing cholangitis; biliary cirrhosis; diabetes mellitus; hyperthyroidism; chronic pancreatitis; heavy alcohol consumption; smoking; and past exposure to Thorotrast (a contrast agent). Premalignant lesions of the bile duct include biliary intraepithelial neoplasia and intraductal papillary neoplasia of the biliary system (biliary papillomatosis). In Southeast Asia, hepatolithiasis, chronic typhoid carriage, and infection of the bile ducts with helminths *(Clonorchis sinensis, Opisthorchis viverrini)* are associated with an increased risk of cholangiocarcinoma. HCV (and possibly HBV) infection, cirrhosis, HIV infection, MASLD, diabetes mellitus, obesity, and tobacco smoking are risk factors for intrahepatic cholangiocarcinoma.

Staging is important not only because it correlates with the patient's long-term survival but also because it is used to determine which patients should receive adjuvant or neoadjuvant therapy.

Clinical Findings

A. Symptoms and Signs

Progressive jaundice is the most common and usually the first sign of obstruction of the extrahepatic biliary system. Pain in the right upper abdomen with radiation into the back is usually present early in the course of gallbladder carcinoma but occurs later in the course of bile duct carcinoma. Anorexia and weight loss are common and may be associated with fever and chills due to cholangitis. Rarely, hematemesis or melena results from erosion of cancer into a blood vessel (*hemobilia*). Fistula formation between the biliary system and adjacent organs may also occur. The course is usually one of rapid deterioration, with death occurring within a few months.

Physical examination reveals profound jaundice. Pruritus and skin excoriations are common. A palpable gallbladder with obstructive jaundice usually is said to signify malignant disease (**Courvoisier sign**); however, this clinical generalization has been proven to be accurate only about 50% of the time. Intrahepatic cholangiocarcinoma, however, rarely presents with obstructive symptoms. Hepatomegaly due to hypertrophy of the unobstructed liver lobe is usually present and is associated with liver tenderness. Ascites may occur with peritoneal implants.

B. Laboratory Findings

With biliary obstruction, laboratory examination reveals predominantly conjugated hyperbilirubinemia, with total serum bilirubin values ranging from 5 to 30 mg/dL. There is usually concomitant elevation of the alkaline phosphatase and serum cholesterol. AST is normal or minimally elevated. The serum CA 19-9 level is elevated in up to 85% of patients but does not distinguish cholangiocarcinoma from benign biliary stricture or obstruction.

C. Imaging

Ultrasonography and contrast-enhanced, triple-phase, helical CT may show a gallbladder mass in gallbladder carcinoma and intrahepatic mass or biliary dilatation in carcinoma of the bile ducts. CT may also show involved regional lymph nodes and atrophy of a hepatic lobe because of vascular encasement with compensatory hypertrophy of the unaffected lobe. MRI with *magnetic resonance cholangiopancreatography (MRCP)* and gadolinium enhancement permits visualization of the entire biliary tract and detection of vascular invasion and obviates the need for angiography and, in some cases, direct cholangiography; it is the imaging procedure of choice but may understage malignant hilar strictures. The features of intrahepatic cholangiocarcinoma on MRI appear to differ from those of HCC, with contrast washout in the latter but not the former. In indeterminate cases, PET can detect cholangiocarcinomas as small as 1 cm and lymph node and distant metastases, but false-positive results occur. *Endoscopic retrograde cholangiography* or *percutaneous transhepatic cholangiography* with biopsy and cytologic specimens can be helpful for ductular malignancies, although false-negative biopsy and cytology results are common. Digital image analysis and fluorescent in situ hybridization of cytologic specimens for polysomy improve sensitivity. FNA can result in cancer seeding and should be avoided if the cancer is potentially resectable.

Treatment

In young and fit patients, curative surgery for gallbladder carcinoma may be attempted if the cancer is well localized. The 5-year survival rate for carcinoma of the gallbladder invading the lamina propria or muscularis (stage 1, T1a or 1b, N0, M0) is as high as 85% with laparoscopic cholecystectomy but drops to 60%, even with a more extended open resection if there is perimuscular invasion (T2). The role of radical surgery for T3 and T4 tumors is debatable. If the cancer is unresectable at laparotomy, biliary-enteric bypass (eg, Roux-en-Y hepaticojejunostomy) can be performed.

Carcinoma of the bile ducts is curable by surgery in < 10% of cases. If resection margins are negative, the 5-year survival rate may be as high as 47% for intrahepatic cholangiocarcinomas, 41% for hilar cholangiocarcinoma, and 37% for distal cholangiocarcinomas, but the perioperative mortality rate may be as high as 10%. Factors predicting shorter survival for intrahepatic cholangiocarcinoma include large cancer size, multiple cancers, lymph node metastasis, and vascular invasion. Adjuvant chemotherapy with capecitabine has been shown to result in superior overall survival compared with no adjuvant therapy. Palliation can be achieved by placement of a self-expandable metal stent via an endoscopic or percutaneous transhepatic route. Covered metal stents may be more cost-effective than uncovered metal stents because of a longer duration of patency; however, they are associated with a higher rate of stent migration and cholecystitis due to occlusion of the cystic duct and are not associated with longer survival. For perihilar cancers, bilateral stents may be preferable to a unilateral stent when technically feasible. Plastic stents are less expensive initially, but not in the long term, because they are more prone to occlude than metal ones; they may be considered based on local expertise and physician preference. Photodynamic therapy in combination with stent placement prolongs survival when compared with stent placement alone in patients with nonresectable cholangiocarcinoma. Endoscopic retrograde cholangiopancreatography (ERCP)–directed radiofrequency ablation, TACE, and TARE are additional options. Radiotherapy may relieve pain and contribute to biliary decompression. There is limited response to chemotherapy with gemcitabine alone, but the combination of cisplatin and gemcitabine (now given with durvalumab) or capecitabine and gemcitabine prolongs survival in patients with locally advanced or metastatic cholangiocarcinoma. Second-line therapy is with FOLFOX (folinic acid, fluorouracil, and oxaliplatin). Immunotherapy with pembrolizumab has benefit in the 1–2% of cholangiocarcinomas with a mismatch repair deficiency. Pemigatinib, an oral small-molecule inhibitor of fibroblast growth factor receptor (FGFR), has benefit in patients with advanced refractory cholangiocarcinoma harboring an FGFR2 fusion or rearrangement. Few patients survive for > 24 months. Although cholangiocarcinoma is generally considered to be a contraindication to liver transplantation because of rapid cancer recurrence, a 5-year survival rate of 75% has been reported in patients with stage I and II perihilar cholangiocarcinoma undergoing chemoradiation and exploratory laparotomy followed by liver transplantation, and a 5-year survival rate of 67% has been reported in those with intrahepatic cholangiocarcinoma.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

All patients with carcinoma of the biliary tract should be referred to a specialist.

When to Admit

- Biliary obstruction.
- Cholangitis.

CARCINOMA OF THE PANCREAS & AMPULLA OF VATER

ESSENTIALS OF DIAGNOSIS

- Obstructive jaundice (may be painless).
- Enlarged gallbladder (may be painful).
- Upper abdominal pain with radiation to back, weight loss, and thrombophlebitis are usually late manifestations.

General Considerations

Carcinoma is the most common neoplasm of the pancreas. About 75% are in the head and 25% in the body and tail of the organ. Pancreatic carcinomas account for 3% of all cancers and 7% of cancer deaths. The incidence is increasing, especially in women under age 55. **Ampullary carcinomas** are much less common. Risk factors for pancreatic cancer include age, tobacco use (which is thought to cause 20–25% of cases), heavy alcohol use, obesity, chronic pancreatitis, diabetes mellitus, prior abdominal radiation, family history, and possibly gallstones, gastric ulcer, and exposure to arsenic and cadmium. *New-onset diabetes mellitus after age 45 years occasionally heralds the onset of pancreatic cancer*, and weight loss may precede the diagnosis. Although there were signals of risk in older studies, among patients with diabetes, GLP-1–based therapy is not associated with increased risk up to 7 years later. About 7% of patients with pancreatic cancer have a family history of pancreatic cancer in a first-degree relative, compared with 0.6% of control patients. Most pancreatic cancers originate from pancreatic intraepithelial neoplasias, which measure < 5 mm in diameter and can only be seen with a microscope.

In 10–15% of cases, pancreatic cancer occurs as part of a hereditary syndrome, including familial breast cancer (carriers of *BRCA2* have a 7% lifetime risk of pancreatic cancer), hereditary pancreatitis, familial atypical multiple mole melanoma, Peutz-Jeghers syndrome, ataxia-telangiectasia, and Lynch syndrome (hereditary nonpolyposis colorectal cancer).

Neuroendocrine tumors account for 1–2% of pancreatic neoplasms and may be functional (producing gastrin, insulin, glucagon, vasoactive intestinal peptide, somatostatin, growth hormone–releasing hormone, ACTH, and others) or nonfunctional. Cystic neoplasms account for < 10% of pancreatic neoplasms, but they are important because pancreatic cysts are common and may be mistaken for pseudocysts. *A cystic neoplasm should be suspected when a cystic lesion in the pancreas is found in the absence of a history of pancreatitis or trauma.* At least 15% of all pancreatic cysts are neoplasms. Serous cystadenomas (which account for 32–39% of cystic pancreatic neoplasms) are benign. However, mucinous cystic neoplasms (defined by the presence of ovarian stroma and accounting for 10–45% of cystic pancreatic neoplasms), intraductal papillary mucinous neoplasms (21–33% of cystic pancreatic neoplasms), solid pseudopapillary tumors (< 5%, primarily in young women), and cystic islet cell tumors (3–5%) may be malignant. Their prognoses are better than the prognosis of pancreatic adenocarcinoma, unless the cystic neoplasm is at least locally advanced.

Clinical Findings

A. Symptoms and Signs

Pain is present in over 70% of cases and is often vague, diffuse, and located in the epigastrium or, when the lesion is in the tail, located in the left upper quadrant of the abdomen. Radiation of pain into the back is common and sometimes predominates. Sitting up and leaning forward may afford some relief, and this usually indicates that the lesion has spread beyond the pancreas and is inoperable. Diarrhea, perhaps due to maldigestion, is an occasional early symptom. Migratory thrombophlebitis is a rare sign. Weight loss is a common finding and may be associated with depression. Hyperglycemia and decreases in subcutaneous abdominal fat and serum lipid levels have been reported to precede a diagnosis of pancreatic cancer. Occasional patients (often aged 40 years or older) present with acute pancreatitis in the absence of an alternative cause. Jaundice is usually due to biliary obstruction by a cancer in the pancreatic head. A palpable gallbladder is also indicative of obstruction by a neoplasm (Courvoisier sign), but there are frequent exceptions. A hard, fixed, occasionally tender mass may be present. In advanced cases, a hard periumbilical (Sister Mary Joseph) nodule may be palpable.

B. Laboratory Findings

There may be mild anemia. The serum lipase or amylase level is occasionally elevated. Liver biochemical tests may suggest obstructive jaundice. Steatorrhea in the absence of jaundice is uncommon. Occult blood in the stool is suggestive of carcinoma of the ampulla of Vater (the combination of biliary obstruction and bleeding may give the stools a distinctive silver appearance). CA 19-9, with a sensitivity of 70% and a specificity of 87%, has generally not proven useful for early detection of pancreatic cancer; increased values are also found in acute and chronic pancreatitis and cholangitis. Plasma chromogranin A levels are elevated in 88–100% of patients with pancreatic neuroendocrine tumors (NETs) but this can be elevated among users of proton pump inhibitors (PPIs).

C. Imaging

Multiphase thin-cut helical (pancreatic protocol) CT is generally the initial diagnostic procedure and detects a mass in 76–96% of cases. CT identifies metastases, delineates the extent of the tumor, and allows percutaneous FNA for cytologic studies and tumor markers. MRI is an alternative to CT. Ultrasonography is not reliable because of interference by intestinal gas. PET is a sensitive technique for detecting pancreatic cancer and metastases, but PET-CT is not a routine staging procedure. Selective celiac and superior mesenteric arteriography may demonstrate vessel invasion by cancer, a finding that would preclude attempts at surgical resection, but it is used uncommonly since the advent of multiphase helical CT. EUS is more sensitive than CT for detecting pancreatic cancer and is equivalent to CT for determining nodal involvement and resectability. *A normal EUS excludes pancreatic cancer.* EUS may also be used to guide FNA or biopsy for tissue diagnosis, tumor markers, and DNA analysis. In some centers, pancreatoscopy or intraductal ultrasonography is used to evaluate filling defects in the pancreatic duct and assess resectability of intraductal papillary mucinous cancers. With obstruction of the splenic vein, splenomegaly or gastric varices are present, the latter detected by endoscopy, EUS, or angiography.

Cystic neoplasms can be distinguished by their appearance on CT, EUS, and ERCP and features of the cyst fluid on gross, cytologic, and genetic analysis. For example, serous cystadenomas may have a central scar or honeycomb appearance; mucinous cystadenomas are unilocular or multilocular and contain mucin-rich fluid with low glucose levels (< 25 mg/dL [1.4 mmol/L]), high carcinoembryonic antigen levels (> 192 ng/mL [192 mcg/L]), and *KRAS* and *GNAS* pathogenic variants; and intraductal papillary mucinous neoplasms are associated with a dilated pancreatic duct and extrusion of gelatinous material from the ampulla.

Staging

The TNM system is the commonly used classification to stage pancreatic cancer. Staging correlates with the patient's long-term survival and is used to determine which patients should receive adjuvant or neoadjuvant therapy. Localized pancreatic cancer includes *resectable, borderline resectable* (involving major vascular structures), and *locally advanced (unresectable)* disease. Over 30% of patients present with locally advanced disease and over 50% with *metastatic disease.*

Treatment

Abdominal exploration is usually necessary when cytologic diagnosis cannot be made or if resection is to be attempted (in up to 30% of patients with pancreatic carcinoma). In a patient with a localized mass in the head of the pancreas and without jaundice, laparoscopy may detect tiny peritoneal or liver metastases and thereby avoid resection in 4–13% of patients. *Radical pancreaticoduodenal (Whipple) resection* is indicated for cancers strictly limited to the head of the pancreas, periampullary area, and duodenum (T1, N0, M0). The 5-year survival rate is 20–25% in this group and as high as 40% in those with negative resection margins and without lymph node involvement. Preoperative endoscopic decompression of an obstructed bile duct is often achieved with a plastic stent or short metal stent but does not reduce operative mortality and is associated with complications.

The best surgical results are achieved at centers that specialize in the multidisciplinary treatment of pancreatic cancer. Adjuvant chemotherapy with gemcitabine, 5-fluorouracil, or gemcitabine with capecitabine is superior to no adjuvant therapy. Gemcitabine with capecitabine and a modified FOLFIRINOX (5-fluorouracil, leucovorin, irinotecan, oxaliplatin) regimen have been found to be superior to gemcitabine alone. The role of adjuvant chemoradiation is controversial but often used in the United States. Neoadjuvant chemotherapy with or without radiation is increasingly being used to downstage patients and in those with resectable cancer. Common chemotherapy regimens for this purpose include FOLFIRINOX and gemcitabine with nanoparticle albumin-bound (nab)-paclitaxel. *Chemoradiotherapy downstages about 30% of patients with locally advanced disease to allow resection.*

When resection is not feasible, *endoscopic stenting of the bile duct* is performed to relieve jaundice. A plastic stent has generally been preferred if the patient's anticipated survival is < 6 months (or if surgery is planned). A metal stent is preferred when anticipated survival is 6 months or greater. Whether covered metal stents designed to prevent cancer ingrowth offer an advantage over uncovered stents is uncertain because covered stents are associated with higher rates of migration and acute cholecystitis due to occlusion of the cystic duct. Surgical biliary bypass may be considered in patients expected to survive at least 6 months. Surgical duodenal bypass may be considered in patients in whom duodenal obstruction is expected to develop; alternatively, endoscopic placement of a self-expandable duodenal stent may be feasible. Chemoradiation may be used for palliation of unresectable cancer confined to the pancreas.

In metastatic pancreatic cancer, improved response rates have been reported with FOLFIRINOX and with the combination of gemcitabine and nab-paclitaxel. In patients who have received prior chemotherapy, a regimen of 5-fluorouracil and leucovorin in combination with nanoliposomal irinotecan has resulted in improved survival compared with 5-fluorouracil and leucovorin alone. Celiac plexus nerve block (see Chapter 5) done under CT or EUS guidance or thoracoscopic splanchnicectomy may improve pain control.

Surgical resection is the treatment of choice for NETs, when feasible. Lesions that are < 1 cm in diameter and nonfunctioning without evidence of local invasion or metastasis may be followed expectantly. Metastatic disease may be controlled with long-acting somatostatin analogs, interferon, chemotherapy, peptide-receptor radionuclide therapy (PRRT), and chemoembolization.

There is a consensus that asymptomatic incidental pancreatic cysts 2 cm or smaller are at low risk for harboring invasive carcinoma. The cysts may be monitored by imaging tests (MRI) in 1 year and then every 2 years if no changes are observed, with EUS and FNA performed if a cyst enlarges to 2 cm or more. The development of a high-risk feature (dilated main pancreatic duct, presence of a solid component ≥ 5 mm, suspicious cytology) should prompt consideration of surgery. The optimal approach is uncertain, however, and the newest guidelines emphasize the importance of shared decision-making. Surgical resection is indicated for mucinous cystic neoplasms, symptomatic serous cystadenomas, solid pseudopapillary tumors (which have a 15% risk of malignant transformation), and cystic tumors larger than 2 cm in diameter that remain undefined after helical CT, EUS, and diagnostic aspiration. All intraductal papillary mucinous neoplasms of the main pancreatic duct should be resected, but those of branch ducts may be monitored with serial imaging if they (1) are asymptomatic and exhibit benign features; (2) have a diameter < 3 cm (some authorities recommend a diameter of 1.5 cm or smaller, but even lesions 3 cm or larger may be monitored in older adults with no other worrisome cyst features); and (3) lack nonenhancing mural nodules, a thick wall, or an abrupt change in the caliber of the pancreatic duct with distal pancreatic atrophy, or possibly bile duct dilatation and gallbladder adenomyomatosis. Most lesions with such benign features remain stable on follow-up, but a risk of malignancy persists for > 10 years. Moreover, the risk of pancreatic ductal carcinoma and of nonpancreatic cancers is also increased in this group of patients. In the absence of locally advanced disease, survival is higher for malignant cystic neoplasms than for adenocarcinomas. Endoscopic resection or ablation, with temporary placement of a pancreatic duct stent, may be feasible for ampullary adenomas, but patients must be followed for recurrence.

Prognosis

Carcinoma of the pancreas, especially in the body or tail, has a poor prognosis; 80–85% of patients present with advanced unresectable disease, and the reported 5-year survival rate is 2–5%. From 1999 to 2020, mortality from pancreatic cancer in the United States has slowly *increased* to an age-adjusted mortality rate of 11.1 per 100,000. Obesity may adversely affect mortality in Western countries. Tumors of the ampulla have a better prognosis, with a reported 5-year survival rate of 20–40% after resection; jaundice and lymph node involvement are adverse prognostic factors. In carefully selected patients, resection of cancer of the pancreatic head is feasible and results in reasonable survival. In persons with a family history of pancreatic cancer in at least two first-degree relatives, or with a genetic syndrome associated with an increased risk of pancreatic cancer, annual screening with EUS and alternating with MRI should be considered, generally beginning at age 50 years (age 40 years in *CKDN2A* or *PRSS1* pathogenic variant carriers and age 35 years in those with Peutz-Jeghers syndrome) or 10 years before the age at which pancreatic cancer was first diagnosed in a family member.

For those patients whose disease progresses despite treatment, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

All patients with carcinoma involving the pancreas and the ampulla of Vater should be referred to a specialist.

When to Admit

Patients who require surgery and other interventions should be hospitalized.

ALIMENTARY TRACT CANCERS

ESOPHAGEAL CANCER

ESSENTIALS OF DIAGNOSIS

- Progressive dysphagia to solid food.
- Weight loss common.
- Endoscopy with biopsy establishes diagnosis.

General Considerations

Esophageal cancer usually develops in persons 50–70 years of age. In the United States, there were an estimated 22,370 new cases of esophageal cancer resulting in 16,130 deaths in 2024. The ratio for new cases in men versus women is 4:1. There are two histologic types: squamous cell carcinoma and adenocarcinoma, and their incidence has significant geographic variation. **Squamous cell carcinoma (SCC)** is associated with low socioeconomic status; consumption of tobacco, alcohol, hot beverages, and nitrosamines; and poor nutritional status. It accounts for over 90% of cases of esophageal cancer in Eastern and Southeast Asia and sub-Saharan Africa. **Adenocarcinoma** is associated with age; obesity; smoking; and chronic GERD with Barrett metaplasia. Adenocarcinomas make up most new cases of esophageal cancer in North America and Northern and Western Europe. Most (90%) squamous cell carcinomas occur in the upper and middle third of the esophagus, whereas adenocarcinomas are more common in the distal esophagus and gastroesophageal junction.

Clinical Findings

A. Symptoms and Signs

Approximately 30–40% of patients with esophageal cancer present with stage IV, “incurable” disease. While early symptoms are nonspecific and subtle, over 90% eventually have solid food dysphagia, which progresses over weeks to months. Odynophagia is sometimes present. Significant weight loss is common. Local tumor extension into the tracheobronchial tree may result in a tracheoesophageal fistula, characterized by coughing on swallowing or by pneumonia.

B. Laboratory Findings

Laboratory findings are nonspecific. Anemia related to chronic disease or occult blood loss is common. Hypoalbuminemia may result from malnutrition.

C. Imaging

A barium esophagogram may be the first study obtained to evaluate dysphagia. The appearance of a polypoid, obstructive, or ulcerative lesion suggests carcinoma and requires endoscopic evaluation. *Even lesions believed to be benign by radiography warrant endoscopic evaluation.* Chest radiographs may show adenopathy, a widened mediastinum, pulmonary or bony metastases, or signs of tracheoesophageal fistula such as pneumonia.

D. Upper Endoscopy

Endoscopy with biopsy establishes the diagnosis of esophageal carcinoma with a high degree of reliability. In some cases, significant submucosal spread of the tumor may yield nondiagnostic mucosal biopsies. Repeat biopsy may be necessary.

Staging

After confirmation of the diagnosis of esophageal carcinoma at esophagoscopy, the stage of the disease should be determined to guide therapy. Patients should undergo evaluation with contrast CT of the chest, abdomen, and pelvis to look for local tumor extension, lymphadenopathy, and metastases (eg, pulmonary or hepatic). If there is no evidence of extensive local spread or distant metastases on CT, then EUS with guided fine-needle biopsy of suspicious lymph nodes should be performed to evaluate the locoregional stage. PET with fluorodeoxyglucose or integrated PET-CT imaging is indicated to look for regional or distant spread prior to invasive surgery.

Differential Diagnosis

Esophageal carcinoma must be distinguished from other causes of progressive dysphagia, including peptic stricture, achalasia, and adenocarcinoma of the gastric cardia with esophageal involvement. Benign-appearing peptic strictures should be biopsied at presentation to exclude occult malignancy.

Treatment

The approach to esophageal cancer treatment depends on the cancer stage and location, patient preference and functional status, and expertise of treating gastroenterologists, surgeons, oncologists, and radiation oncologists. It is helpful to classify patients into those with *early-stage (“curable”) disease* and those with *advanced-stage (“incurable”) disease.*

Studies of the treatment of early-stage esophageal cancer often have combined both SCCs and adenocarcinomas; however, their risk factors, pathobiology, and responses to treatment differ substantially. SCCs are the most common cancer of the cervical esophagus and typically more radiosensitive than adenocarcinoma. Because surgical resection of a cervical esophagus tumor often requires laryngectomy and neck dissection with attendant comorbidities, chemoradiation usually is preferred over surgery for curative intent treatment of SCC of the cervical esophagus. The discussion below applies to treatment of tumors arising in the thoracic esophagus and gastroesophageal junction.

A. Therapy for "Curable" Disease

Superficial esophageal cancers confined to the epithelium (high-grade dysplasia or carcinoma in situ [Tis]), lamina propria (T1a), or submucosa (T1b) are increasingly recognized in endoscopic screening and surveillance programs. Esophagectomy achieves high cure rates for superficial tumors but is associated with mortality (2%) and morbidity. If performed by experienced clinicians, endoscopic mucosal resection of Tis and T1a cancers achieves equivalent long-term survival with less morbidity (see Barrett Esophagus, Chapter 17). Esophagectomy is usually recommended for high risk T1a tumors (with poor differentiation or lymphovascular invasion) and T1b tumors because of higher rates of lymph node metastasis, but endoscopic resection may be considered in high operative risk patients.

There are multiple surgical approaches to the resection of invasive but potentially "curable" esophageal cancers (stage IB, II, IIIA, or IIIB). Accepted techniques include en bloc transthoracic excision of the esophagus with extended lymph node dissection, transhiatal esophagogastrectomy (entailing laparotomy with cervical anastomosis), and minimally invasive esophagectomy techniques. Meta-analysis data suggest equivalent oncologic outcomes from minimally invasive esophagectomy and conventional open techniques, although there are fewer postoperative complications and shorter hospital stays with the laparoscopic approach. Multiple meta-analyses have shown that, regardless of surgery type, surgery at a high-volume hospital is associated with decreased perioperative mortality.

Patients with stage I tumors have high cure rates with surgery alone and do not require radiation or chemotherapy. For stage II T2N0 tumors, whether radiation, chemotherapy, or both are required in addition to surgery is a subject of ongoing debate. For patients with T3N0 tumors (stage IIB) or tumors of any T stage with regional lymph node metastases (stage III), cure following surgery alone is < 20%, and one of the following additional therapies is indicated.

1. Surgery with perioperative chemotherapy—For esophageal and gastroesophageal junction adenocarcinomas, the phase 3 ESOPEC trial showed a survival benefit for perioperative FLOT (fluorouracil, leucovorin, oxaliplatin, and docetaxel) chemotherapy compared to neoadjuvant chemoradiotherapy. Based on this study, four cycles of preoperative plus four cycles of postoperative triplet FLOT chemotherapy is the standard of care.

2. Surgery with neoadjuvant chemoradiation therapy—Patients with stage IIB and III tumors who do not tolerate the intensive preoperative and postoperative triplet chemotherapy regimen should be considered for neoadjuvant chemoradiation with lower chemotherapy doses. The preferred regimen uses radiation therapy concurrently with weekly carboplatin plus paclitaxel (administered at lower, radiosensitizing doses); however, FOLFOX is an alternative with greater efficacy though greater toxicity (Table 44–2). Radiation techniques that are less toxic, such as intensity-modulated radiation therapy or proton beam therapy, should be considered. Following completion of neoadjuvant chemoradiation and surgical resection, for patients with residual cancer, adjuvant immunotherapy with nivolumab for 1 year is recommended.

3. Chemotherapy plus radiation therapy without surgery—Concurrent chemotherapy plus radiation therapy achieves long-term survival in up to 25% of patients and is superior to radiation alone. Chemoradiation alone should be considered in patients with localized disease (stage II or IIIA) who are poor surgical candidates due to serious medical illness or poor functional status (Eastern Cooperative Oncology Group score > 2). Patients with cervical esophageal cancers, which appear similar biologically to head and neck cancers and in whom surgery is highly morbid and typically not recommended, also should be considered for definitive chemoradiation.

4. Supportive care during definitive therapy—Patients with significant tumor obstruction may require percutaneous gastric or jejunal tube placement to maintain adequate hydration and nutrition during neoadjuvant chemoradiation or chemotherapy. Multidisciplinary consultation is required to determine the optimal procedure and to optimize perioperative nutrition.

B. Therapy for "Incurable" Disease

More than half of patients have either locally extensive tumor spread (T4b) that is unresectable or distant metastases (M1) at the time of diagnosis. Surgery is not warranted in these patients. Since prolonged survival can be achieved in few patients, *the primary goal is to provide relief from dysphagia and pain, to optimize quality of life, and to minimize treatment side effects*. The optimal palliative approach depends on the presence or absence of metastatic disease, expected survival, patient preference, and molecular characteristics of the tumor.

1. Chemotherapy or chemoradiation—Combined radiation therapy and chemotherapy may achieve palliation in two-thirds of patients but is associated with significant side effects. It should be considered for patients with locally advanced tumors without distant metastases who have good functional status and no significant medical problems, in whom prolonged survival may be achieved. Multiagent chemotherapy may be considered in patients with metastatic disease who still have good functional status and expected survival of at least several months.

The systemic therapy options are the same for metastatic esophageal, gastroesophageal junction, and gastric cancers (Table 44–2). Choice of treatment is increasingly influenced by the results of molecular testing, including PD-L1 expression, mismatch repair/microsatellite instability (MMR/MSI) and, for adenocarcinomas, *HER2* amplification and Claudin 18.2 expression testing. In patients with amplification of the *HER2* gene (approximately 15% of cases), addition of the monoclonal antibody trastuzumab (see Chapter 19) along with anti-PD-L1 therapy to chemotherapy is associated with prolonged survival (Table 44–8). For patients without *HER2* amplification who have increased PD-L1 expression, the addition of a PD-1 or PD-L1 targeted antibody to chemotherapy improves overall survival. Immunotherapy should also be considered for tumors with either microsatellite instability-high (MSI-H) or deficient mismatch repair (dMMR) protein expression. For adenocarcinomas without *HER2* overexpression that do have Claudin 18.2 expression, the addition of zolbetuximab to chemotherapy prolongs survival. For tumors that have expression of both PD-L1 and Claudin 18.2, the optimal regimen is unknown. For the remainder of metastatic esophageal cancers, a PD-1 or PD-L1 targeted agent should be considered in the second-line or later setting For patients with poor functional status, single-agent therapy with a fluoropyrimidine, a taxane, or irinotecan may be considered.

2. Local therapy for esophageal obstruction—Patients with advanced esophageal cancer often have a poor functional and nutritional status. Radiation therapy alone to the area of esophageal obstruction may afford short-term relief of pain and dysphagia. Rapid palliation of dysphagia may be achieved by peroral placement of permanent expandable wire stents (alone or followed by radiation). However, placement of these stents is complicated by perforation, migration, or tumor ingrowth in up to 40% of cases.

Prognosis

The overall 5-year survival rate of esophageal carcinoma is < 20%. Apart from distant metastasis (M1b), the two most important predictors of poor survival are adjacent mediastinal spread (T4) and lymph node involvement. For those patients whose disease progresses despite chemotherapy, meticulous efforts at palliative care are essential (see Chapter 5).

When to Refer

- Patients should be referred to a gastroenterologist for evaluation and staging (endoscopy with biopsy, EUS) and palliative endoscopic stenting.
- Patients with curable and resectable disease for whom neoadjuvant therapy may be appropriate (stage IIB or IIIA) should be referred to medical, radiation, and surgical oncologists for consideration of neoadjuvant chemotherapy, chemoradiotherapy, and surgical resection.
- Patients with metastatic disease should be referred to medical and radiation oncologists for consideration of palliative chemotherapy or chemoradiation.
- Patients with metastatic disease and obstructive tumors not amenable to or refractory to palliative radiation or stenting may require referral to an interventional radiologist, gastroenterologist, or surgeon for gastric or jejunal tube placement for hydration and liquid artificial nutrition. Early referral to palliative care may improve symptom management in patients with advanced or metastatic disease.

When to Admit

Patients with high-grade esophageal obstruction with inability to manage oral secretions or maintain hydration should be admitted. Acute complications such as perforation, bleeding, aspiration, or fistula also may require admission.

GASTRIC ADENOCARCINOMA

ESSENTIALS OF DIAGNOSIS

- Dyspeptic symptoms with weight loss in patients over age 40 years.
- Iron deficiency anemia: occult blood in stools.
- Abnormality detected on upper GI series, abdominal CT endoscopy; diagnosis established by endoscopic biopsy.

General Considerations

Gastric adenocarcinoma is the third most common cause of cancer death worldwide. Its main risk factors include increasing age, male sex, certain races (eg, Asian, Black, Lantinx), smoking, and *Helicobacter pylori* infection. Chronic *H pylori* gastritis is the strongest risk factor, increasing the relative risk 3.5- to 20-fold.

The incidence of gastric adenocarcinoma has declined rapidly over the last 70 years, especially in Western countries, perhaps attributable to changes in diet (more fruits and vegetables), increased food refrigeration, reduced toxic environmental exposures, and a decline in *H pylori* infections.

In the United States in 2024, gastric cancer accounted for 1.3% of all new cancers (with an estimated 26,890 incident cases and an estimated 10,880 deaths). The incidence of gastric cancer remains high in Japan and many developing regions, including eastern Asia, Eastern Europe, Chile, Colombia, and Central America.

There are two main histologic variants of gastric cancer: "intestinal-type" (which resembles intestinal cancers in forming glandular structures) and "diffuse" (which is poorly differentiated and lacks glandular formation).

The incidence of *intestinal-type gastric cancer* has declined significantly, but it is still the more common type (70–80%); it occurs twice as often in men as women and primarily affects older people (mean age 68 years). It is estimated that 60–90% of cases may be attributable to *H pylori*. Other risk factors for intestinal-type gastric cancer include pernicious anemia, a history of partial gastric resection > 15 years previously, smoking, and diets that are high in nitrates or salt and low in vitamin C.

Diffuse gastric cancer accounts for 20–30% of gastric cancer cases. In contrast to intestinal-type cancer, it affects men and women equally, occurs more commonly in young people, is not as strongly related to *H pylori* infection, and has a worse prognosis than intestinal-type cancer due to early metastasis. Diffuse gastric cancers are often attributable to acquired or hereditary pathogenic variants in the genes regulating the E-cadherin cell adhesion protein. Hereditary diffuse gastric cancer may arise at a young age, is often multifocal and infiltrating with signet ring cell histology and has a poor prognosis.

Most gastric cancers arise in the body and antrum. These may occur in a variety of morphologic types: (1) polypoid or fungating intraluminal masses; (2) ulcerating masses; (3) diffusely spreading (**linitis plastica**), in which the cancer spreads through the submucosa, resulting in a rigid, atonic stomach with thickened folds (prognosis is dismal); and (4) superficially spreading or "early" gastric cancer—confined to the mucosa or submucosa (with or without lymph node metastases) and associated with a more favorable prognosis.

In contrast to the dramatic decline in cancers of the distal stomach, a rise in incidence of tumors of the gastric cardia has been noted. These tumors have demographic and pathologic features that resemble Barrett-associated esophageal adenocarcinomas (see Esophageal Cancer, above).

Clinical Findings

A. Symptoms and Signs

Gastric carcinoma is generally asymptomatic until quite advanced. Symptoms are nonspecific and are determined in part by the location of the tumor. Dyspepsia, vague epigastric pain, anorexia, early satiety, and weight loss are the presenting symptoms in most patients. Patients may derive initial symptomatic relief from over-the-counter remedies, further delaying diagnosis. Ulcerating lesions can lead to acute GI bleeding with hematemesis or melena. Pyloric obstruction results in postprandial vomiting. Lower esophageal obstruction causes progressive dysphagia. Physical examination is rarely helpful.

B. Laboratory Findings

Iron deficiency anemia due to chronic blood loss or anemia of chronic disease is common. Stool tests may be positive for occult blood. Circulating tumor markers do not have established clinical validity in screening or diagnosis of gastric cancer.

C. Endoscopy

Upper endoscopy should be obtained in all patients over age 60 years with new onset of epigastric symptoms (dyspepsia) and young patients with *"alarm" symptoms (dysphagia, recurrent vomiting, significant weight loss)*, especially in immigrants from countries with a high prevalence of gastric cancer. Endoscopy with biopsies of suspicious lesions is highly sensitive for detecting gastric carcinoma. However, it can be difficult to obtain adequate biopsy specimens in diffuse-type gastric cancer.

D. Imaging

Once a gastric cancer is diagnosed, preoperative evaluation by contrast CT of chest, abdomen, and pelvis and by EUS is indicated to delineate the local extent of the primary tumor as well as to evaluate for nodal or distant metastases. EUS is superior to CT in determining the depth of tumor penetration and is useful for evaluation of early gastric cancers that may be removed by endoscopic mucosal resection. PET or combined PET-CT imaging is recommended for detection of distant metastasis.

Screening

Due to the higher incidence of gastric cancer in East Asia, population-based nationwide screening by upper endoscopy has been implemented in South Korea and Japan. In the United States and other countries with a relatively low incidence of gastric cancer, routine screening for gastric cancer is not recommended but may be considered beginning at age 50 in people who are first-generation immigrants from high-incidence regions and people who belong to racial or ethnic groups who are at increased risk.

Because of its unproven efficacy and cost-effectiveness, screening and treating for *H pylori* infection are not recommended to prevent gastric cancer in asymptomatic US adults (but are recommended in patients who have immigrated from regions with a high incidence of gastric cancer or who have a family history of gastric cancer). However, a 2023 retrospective study of 716,567 patients with *H pylori* in a community-based population found a significant reduction after 8 years in the risk of gastric adenocarcinoma in those who were treated for *H pylori* versus who were untreated (HR 0.37).

Staging

The TNM system used to stage gastric adenocarcinoma correlates with the patient's long-term survival and is used to determine which patients should receive adjuvant or neoadjuvant therapy.

Pathologic review should include (1) grade of tumor, (2) histologic subtype, (3) depth of invasion, (4) whether lymphatic or vascular invasion is present, (5) if there is known metastatic disease, and (6) molecular testing for human epidermal growth factor receptor 2 (HER2) protein overexpression, dMMR proteins or microsatellite instability-high (MSI-H), PD-L1 expression, and Claudin 18.2 expression.

Differential Diagnosis

Ulcerating gastric adenocarcinomas are distinguished from benign gastric ulcers by biopsies. Approximately 3% of gastric ulcers initially believed to be benign later prove to be malignant. All gastric ulcers identified at endoscopy should be biopsied to exclude malignancy. Ulcers that are suspicious for malignancy to the endoscopist or that have atypia or dysplasia on histologic examination warrant repeat endoscopy in 2–3 months to verify healing and exclude malignancy. Nonhealing ulcers should be considered for resection. Infiltrative carcinoma with thickened gastric folds must be distinguished from lymphoma and other hypertrophic gastropathies.

Treatment

Surgical resection, systemic chemotherapy, radiotherapy, immunotherapy, and targeted therapy all have proven efficacy in gastric adenocarcinoma; therefore, multidisciplinary teamwork is paramount to treatment selection. The optimal role and sequencing of adjunctive therapies depends on the location and extent of the cancer, type of surgery, patient comorbidities and performance status, and institutional experience.

A. Curative Surgical Resection

Surgical resection is the primary treatment for nonmetastatic gastric adenocarcinoma and is the only therapy with curative potential. Laparoscopic resection achieves similar outcomes as, and lower overall complication rates than, open gastrectomy. In Japan and in specialized US centers, endoscopic mucosal resection is performed in selected patients with small (< 1–2 cm), early (intramucosal or T1aN0) gastric cancers after careful staging with EUS. A staging laparoscopy prior to definitive surgery should be considered in patients with stage T1b or greater disease without radiographic evidence of distant metastases. *Approximately 25% of patients undergoing surgery will be found to have locally unresectable tumors or peritoneal, hepatic, or distant lymph node metastases that are incurable.* The remaining patients with confirmed localized disease should undergo radical surgical resection. For adenocarcinoma localized to the distal two-thirds of the stomach, a subtotal gastrectomy should be performed. For proximal gastric cancer or diffusely infiltrating disease, total gastrectomy is necessary. The goal of surgery is obtaining negative surgical margins. Vitamin B_{12} supplementation is required after gastrectomy.

B. Perioperative Chemotherapy, Chemoradiation, or Radiation Therapy

For patients with regional lymph node involvement, risk of recurrence with surgery alone is > 60%; therefore, further therapy is recommended. *Multidisciplinary treatment decision-making involving the surgeon, radiation oncologist, and medical oncologist is imperative.* The use of perioperative chemotherapy or adjuvant chemoradiation is associated with improved survival in patients with localized or locoregional gastric adenocarcinoma who undergo surgical resection. Perioperative triplet chemotherapy with FLOT for resectable gastric cancer is recommended for patients who are fit, but is associated with more toxicity than doublet chemotherapy.

Postoperative radiation therapy has not shown a clear benefit in the setting of aggressive surgical nodal dissection but may be beneficial in patients who received a D1 or less nodal dissection or do not achieve an R0 resection.

Tumors arising in the gastroesophageal junction are treated following algorithms for primary esophageal cancers (see Esophageal Cancer, above).

C. Immunotherapies and Targeted Therapies

The advent of immunotherapy has led to significant improvements in outcomes for patients with metastatic gastric cancer. Perioperative immunotherapy for patients with dMMR/MSI-H localized tumors is a promising strategy. Hence, testing for either MMR or MSI status is recommended for all new gastric cancer diagnoses. Among gastric adenocarcinomas, MSI-H/dMMR is found in 8–16% and HER2 amplification in 22%. Systemic therapy regimens are generally the same as those used in esophageal adenocarcinomas.

D. Palliative Modalities

Many patients will be found to have advanced disease that is not amenable to curative intent surgery due to peritoneal or distant metastases or local invasion of other organs. In some of these cases, palliative resection of the tumor nonetheless may be indicated to alleviate pain, bleeding, or obstruction. For patients with unresectable disease and gastric outlet obstruction with good functional status, a surgical diversion with gastrojejunostomy may be indicated to prevent obstruction. Systemic therapy may be considered in patients with metastatic disease who still have good functional status and expected survival of at least several months. Patients with unresected tumors and limited life expectancy may be treated with endoscopic stent therapy, radiation therapy, or angiographic embolization to relieve bleeding or obstruction. The regimens used are the same as those for esophageal and gastroesophageal junction tumors discussed above (Table 44–2).

Prognosis

The 5-year survival for gastric cancer varies greatly by stage, location, and histologic features. Following surgery, the 5-year survival rates for stage IA and IB cancers treated with curative intent are between 60% and 80%, but for stage IIIC cancers, they are as low as 18%. Proximal gastric tumors have a 5-year survival of < 15%, even with apparent localized disease. For those whose disease progresses despite therapy, palliative care is essential (see Chapter 5).

When to Refer

- Patients with dysphagia, weight loss, protracted vomiting, iron deficiency anemia, melena, or new-onset dyspepsia (especially if aged 60 years or older or associated with other alarm symptoms) in whom gastric cancer is suspected should be referred for endoscopy.
- Patients should be referred to a surgeon for attempt at curative resection of stage I, II, or III cancer, including staging laparoscopy if indicated.

- Prior to surgery, patients should be referred to an oncologist to determine the role for perioperative chemotherapy or adjuvant chemoradiation or chemotherapy.
- Patients who have undergone gastrectomy require consultation with a nutritionist due to propensity for malnutrition and complications, such as dumping syndrome and vitamin B_{12} deficiency, postoperatively.
- Patients with unresectable or metastatic disease should be referred to an oncologist for consideration of palliative chemotherapy or chemoradiation. Early referral to palliative care services may also be considered for symptom management in patients with advanced and metastatic disease.

When to Admit

Patients with acute bleeding, protracted vomiting, or inability to maintain hydration or nutrition.

GASTRIC LYMPHOMA

ESSENTIALS OF DIAGNOSIS

- Symptoms of dyspepsia, weight loss, or anemia.
- Distinguish primary gastric lymphoma with adjacent nodal spread from advanced systemic lymphoma with secondary gastric involvement.
- Upper GI series or endoscopy shows thickened folds, ulcer, mass, or infiltrating lesions; diagnosis established by endoscopic biopsy.
- Abdominal CT and EUS required for staging.

General Considerations

Gastric lymphomas may be primary (arising from the gastric mucosa) or may represent a site of secondary involvement in patients with nodal lymphomas. Distinguishing advanced **primary gastric lymphoma** with adjacent nodal spread from **secondary gastric lymphoma** spread from advanced nodal lymphoma is essential because the prognosis and treatment of primary and secondary gastric lymphomas are different. Primary gastric lymphoma is the second most common gastric malignancy, accounting for 3–5% of gastric cancers. More than 95% of these are non-Hodgkin B-cell lymphomas mainly consisting of either (1) **mucosa-associated lymphoid tissue (MALT)-type lymphoma** or (2) **diffuse large B-cell lymphoma**. Over 90% of low-grade primary gastric MALT-type lymphomas are associated with *H pylori* infection. *H pylori* leads to chronic inflammation, producing lymphoid tissue in the stomach mucosa (MALT) that can lead to malignant transformation.

Clinical Findings & Staging

The clinical presentation and endoscopic appearance of gastric lymphoma are like those of adenocarcinoma, which makes pathologic review imperative. Most patients have abdominal pain, weight loss, or bleeding. Patients with diffuse large B-cell lymphoma are more likely to have systemic symptoms.

At endoscopy, lymphoma may appear as an ulcer, mass, or diffusely infiltrating lesion. The diagnosis is established with endoscopic biopsy; FNA biopsy is not adequate. Since the disease can be multifocal, biopsies of both suspicious and normal-appearing areas are recommended. Biopsy specimens should be tested for *H pylori* and, if positive, for t(11;18) via PCR or fluorescence in situ hybridization (FISH). EUS is the most sensitive test for determining the depth of invasion and presence of perigastric lymphadenopathy. All patients should undergo staging with CT scanning of chest, abdomen, and pelvis.

MALT-type lymphomas—For gastric MALT lymphomas, the Lugano staging system is most frequently used. Stage I is confined to the GI tract, stage II involves local or regional lymph nodes, stage IIE has invasion of adjacent organs or tissues, and stage IV has distant metastases. There is no stage III.

Diffuse large B-cell lymphomas—For patients with diffuse large B-cell lymphomas involving the stomach, combination PET-CT imaging, bone marrow biopsy with aspirate, tumor lysis laboratory tests, and hepatitis B and HIV serologies may be required for staging and treatment planning (see Chapter 15).

Treatment

Treatment of primary gastric lymphomas depends on the tumor histology, grade, and stage.

A. MALT-Type Lymphomas

Those that are low-grade and localized to the stomach wall (stage I) or perigastric lymph nodes (stage IIE1) have an excellent prognosis. Patients with primary gastric MALT lymphoma should be tested for *H pylori* infection and treated if positive. Complete lymphoma regression after successful *H pylori* eradication occurs in approximately 75% of cases of stage I and approximately 55% of stage IIE low-grade lymphoma. Remission may take as long as a year, and relapse occurs in about 2% of cases per year.

Failure of antibiotic treatment to achieve lymphoma regression may be due to genetic factors. Rates of remission after *H pylori* eradication are lower in patients whose tumors harbor specific gene translocations, including t(11;18) (API2-MALT1), t(1;14), or t(14;18). Of cancers positive for t(11;18), 95% do not respond to antibiotics. Patients with localized marginal zone MALT-type lymphomas who are not infected with *H pylori* or do not respond to *H pylori* antibiotic therapy may be treated with radiation therapy.

Endoscopic surveillance after antibiotic or radiation treatment is recommended every 3–6 months for 5 years to evaluate for recurrence. The long-term survival of low-grade MALT stage I lymphoma is over 90% and for stage II is 35–65%. Surgical resection is *not* recommended.

B. Diffuse Large B-Cell Lymphoma

Diffuse large B-cell lymphomas (or other higher-grade lymphomas with secondary GI involvement) usually present at an advanced stage with widely disseminated disease and are treated according to stage and subtype of lymphoma (see Chapter 15).

Advanced-stage disease can be treated with chemoimmunotherapy or radiation therapy for GI bleeding, threatened end-organ function, bulky disease, or progression. Diffuse large B-cell lymphoma has been successfully treated with two chemotherapeutic options (cyclophosphamide-doxorubicin-vincristine-prednisone [CHOP] or rituximab-CHOP). The presence of perigastric lymph nodes and the degree of tumor infiltration of the gastric wall are indications to consider including radiotherapy in the treatment.

GASTROINTESTINAL MESENCHYMAL TUMORS

Pathobiology & Diagnosis

GI mesenchymal tumors (stromal tumors, leiomyomas, and schwannomas) derive from mesenchymal stem cells. The most common are **GI stromal tumors (GISTs)**, which originate from interstitial cells of Cajal. GISTs occur most commonly in the stomach (60%). Most cases are sporadic, but about 5% of cases are part of familial genetic syndromes. GISTs are potentially malignant and have an unpredictable evolution. Determination of the GIST molecular subtype upon diagnosis is important because it informs therapeutic decisions in both the adjuvant and metastatic setting. Approximately 80–90% of GISTs have gain-of-function mutations in *KIT*, a receptor tyrosine kinase, or in PDGFRα, platelet-derived growth factor α.

Mesenchymal tumors may cause symptoms (most commonly bleeding, pain, or obstruction) or may be discovered incidentally on imaging studies or endoscopy. At endoscopy, they appear as a submucosal mass that may have central umbilication or ulceration. EUS with guided FNA biopsy is the optimal study for diagnosing gastric mesenchymal tumors and distinguishing them from other submucosal lesions. Percutaneous biopsy is not recommended due to risk of bleeding or intra-abdominal seeding. CT of the abdomen and pelvis with contrast, MRI, and PET imaging are useful in the diagnosis and staging. PET imaging also may be useful to monitor response to treatment.

It is difficult to distinguish benign from malignant tumors by EUS appearance. In general, lesions are more likely benign if they are smaller than 2 cm, have a smooth border, and have a homogeneous echo pattern on EUS. But all GISTs have malignant potential, and the risk of developing metastasis is increased with tumor size > 2 cm, nongastric location, and mitotic index > 5 mitoses per 50 HPF.

Treatment

A. Localized Treatment

Complete surgical resection, whether by laparotomy or laparoscopy, is the only potentially curative treatment of localized GISTs. Surgical resection is recommended for tumors that are 2 cm or larger, or are increasing in size, suspicious for malignancy on EUS, or symptomatic. The management of asymptomatic gastric lesions 2 cm or smaller depends on the EUS features. If no high-risk features are noted, endoscopic surveillance with serial EUS can be pursued. Because of the low but real long-term risk of malignancy, surgical resection should be considered in younger, otherwise healthy patients.

B. Systemic Treatment

The introduction of effective molecularly targeted therapies for GISTs has dramatically changed the clinical management and prognosis for patients with intermediate- and high-risk resected GISTs, as well as those with locally advanced and metastatic disease. Molecular characterization is imperative in all cases being considered for systemic therapy. The tyrosine kinase inhibitor imatinib is effective against the most common pathogenic mutations seen in GISTs, including *KIT* and some *PDGFRα* mutations. Neoadjuvant therapy with imatinib may be considered for patients with localized GIST tumors who are deemed to be at high risk for incomplete resection because of comorbidities, tumor size, or tumor location. Adjuvant therapy with imatinib delays recurrence and prolongs survival for most mutations, but it is not likely to be curative. For metastatic GISTs, imatinib has become the standard first-line treatment, inducing disease control in up to 80–85% of patients, with a median survival of almost 5 years. Patients who subsequently experience disease progression on imatinib therapy may be treated with second-, third-, and fourth-line therapy with sunitinib, regorafenib, and ripretinib, respectively. Untreated metastatic GIST tumors are aggressive and carry a poor prognosis.

In the subset of tumors that have the *PDGFRα* D842V pathogenic variant, the KIT and PDGFRα inhibitor avapritinib results in an approximate 90% disease control rate. The role of immunotherapies for mesenchymal tumors is being investigated.

MALIGNANCIES OF THE SMALL INTESTINE

The frequency of different tumor types varies by location within the small intestine. Adenocarcinomas are most common in the duodenum and jejunum and NETs, in the ileum. Lymphomas and sarcomas each have similar incidences in the various segments of the small intestine.

1. Small Intestinal Adenocarcinomas

These cancers often present with abdominal pain and nausea. They are rare, with approximately 12,000 new diagnoses estimated for 2024 in the United States, and most often diagnosed at stage III or IV. The duodenum is the most common site of small bowel adenocarcinoma, specifically the periampullary region. **Ampullary carcinomas** may present with GI bleeding or jaundice due to bile duct obstruction. Surgical resection of early lesions is curative in up to 40% of patients.

Most cases of **nonampullary adenocarcinomas** present with symptoms of obstruction, acute or chronic GI bleeding, or weight loss. Nonspecific findings on cross-sectional imaging and difficulty of endoscopic evaluation often delay diagnosis. For localized disease resection is potentially curative. The benefit of adjuvant therapy after resection of stage II or III tumors is unclear, but it is generally administered using chemotherapy agents active in colorectal cancer. For advanced/unresectable disease, first-line doublet chemotherapy extrapolated from colorectal cancer regimens is standard. Small intestinal adenocarcinoma should be evaluated for MMR/MSI status. Pembrolizumab is an accepted treatment modality for mismatch repair-deficient tumors; more trials with immunotherapy are underway.

Huang J et al; NCD Global Health Research Group, Association of Pacific Rim Universities. Incidence, risk factors and temporal trends of small intestinal cancer: a global analysis of cancer registries . Gastroenterology. 2023;165:600. [PMID: 37277079]

National Comprehensive Cancer Network. Small Bowel Adenocarcinoma, Version 4.2024, NCCN Clinical Practice Guidelines in Oncology. https://www.nccn.org/professionals/physician_gls/pdf/small_bowel.pdf

2. Small Intestinal Lymphomas

Lymphomas may arise primarily in the GI tract (see Gastric Lymphomas above) or may involve it secondarily in patients with disseminated lymphoma. There is an increased incidence of small intestinal lymphomas in patients with AIDS, Crohn disease, and those receiving immunosuppressive therapy. The most common histologic subtypes are non-Hodgkin extranodal marginal zone (MALT) B-cell lymphomas and diffuse large B-cell lymphomas. However, enteropathy-associated T-cell lymphoma (sometimes associated with celiac disease) appears to be increasing in incidence in the United States. In the Middle East, lymphomas may arise in the setting of immunoproliferative small intestinal disease. Other types of intestinal lymphomas include primary intestinal follicular cell lymphoma, mantle cell lymphoma, post-transplant lymphoproliferative disorder, and Burkitt lymphoma (see Chapter 15).

Presenting symptoms or signs of primary small bowel lymphoma include abdominal pain, weight loss, nausea and vomiting, distention, anemia, and occult blood in the stool. Fevers are unusual. Protein-losing enteropathy may result in hypoalbuminemia. CT enterography helps localize the site of the lesion. Diagnosis requires endoscopic, percutaneous, or laparoscopic biopsy. Imaging and possibly bone marrow biopsy are required to determine stage.

Treatment depends on the tumor histologic subtype and stage of disease (see Chapter 15). If feasible, surgical resection of localized primary intestinal lymphoma may be appropriate. Following resection with negative margins, the role of adjuvant chemotherapy in patients with limited disease (stage IE) is unclear. Locoregional radiation should be considered if surgical margins are positive. Patients with more extensive disease generally are treated according to the tumor histology.

Small S et al. B cell lymphomas of the GI tract. Curr Gastroenterol Rep. 2021;23:9. [PMID: 33963950]

3. Small Intestine Sarcoma

Sarcomas constitute approximately 10% of small bowel neoplasms and are commonly found in the jejunum and ileum. Most arise from stromal tumors (GISTs, see Gastrointestinal Mesenchymal Tumors, above); a minority arise from smooth muscle tumors (**leiomyosarcomas**). Common symptoms of small intestine sarcoma include pain, weight loss, bleeding, and perforation. As the lesions tend to enlarge extraluminally, obstruction is rare.

COLORECTAL CANCER

ESSENTIALS OF DIAGNOSIS

- Personal or family history of adenomatous or serrated polyps or colorectal cancer (CRC) is an important risk factor.
- Symptoms or signs depend on tumor location.
- Proximal colon: fecal occult blood, anemia.
- Distal colon: change in bowel habits, hematochezia.
- Diagnosis established by colonoscopy with biopsy.

General Considerations

CRC is the second leading cause of death due to malignancy in the United States. CRC will develop in approximately 4.1% of Americans and has a 5-year survival rate of 65%. In 2024 in the United States, there were estimated to be 106,590 new colon cancer cases (54,201 in men, 52,320 in women) and 46,220 new rectal cancer cases (27,330 in men, 18,890 in women), with an estimated 53,010 deaths. Over the last 10 years, CRC incidence has declined by 1.7% per year and mortality by 3.2% per year, which is attributed to population-based CRC screening. The percentage of US adults aged 50–75 years who were up-to-date with recommended CRC screening was 71.8% in 2021.

CRCs are almost all adenocarcinomas, which tend to form bulky exophytic masses or annular constricting lesions. Most are thought to arise from malignant transformation of an **adenomatous polyp** (tubular, tubulovillous, or villous adenoma) or **serrated polyp** (hyperplastic polyp, traditional serrated adenoma, or sessile serrated adenoma). Polyps that are "advanced" (ie, polyps at least 1 cm in size, adenomas with villous features or high-grade dysplasia, or serrated polyps with dysplasia) are associated with a greater risk of cancer.

Approximately 85% of sporadic CRC arise from adenomatous polyps. They have loss of function of one or more tumor suppressor genes (eg, p53, APC, or DCC) due to a combination of spontaneous pathologic variants of one allele combined with chromosomal instability and aneuploidy (abnormal DNA content) that leads to deletion and loss of heterozygosity of the other allele (eg, 5q, 17q, or 18p deletion). Activation of oncogenes such as *KRAS* and *BRAF* is present in a subset of cancers with prognostic and therapeutic implications discussed further below.

Another 10–20% of CRC arise from serrated polyps, most of which have hypermethylation of CpG-rich promoter regions. This leads to inactivation of the DNA mismatch repair (MMR) gene *MLH1*, resulting in microsatellite instability (MSI-high [or MSI-H]) (the presence of a high number of insertions or deletions at repetitive DNA units) and activation of pathogenic variants of the *BRAF* gene. The vast majority of MSI-H tumors are due to loss of a mismatch repair (MMR) protein, which can be assessed by IHC staining. Tumors lacking staining for an MMR protein are referred to as mismatch repair deficient (dMMR). Serrated CRC have distinct clinical and pathologic characteristics, including diploid DNA content, predominance in the proximal colon, poor differentiation, and more favorable prognosis.

Finally, up to 5% of CRC are caused by inherited pathogenic germline variants resulting in **polyposis syndromes (eg, familial adenomatous polyposis)** or **Lynch syndrome**. These conditions are discussed further below and in Chapter 17.

Risk Factors

Several factors increase the risk of developing CRC, including smoking, consumption of red and processed meats, alcohol intake, diabetes mellitus, physical inactivity, obesity, and history of IBD or primary sclerosing cholangitis. However, 75% of all cases occur in people with no known predisposing factors.

A. Age

The incidence of CRC rises sharply after age 45 years, and 88% of cases occur in persons over the age of 50 years. The median age at diagnosis is 66 years for men and 69 years for women. From the mid-1990s to the 2010s, CRC rates had been increasing in adults ages 20–50 while they decreased in adults over age 50, likely due to CRC screening programs. During the most recent period of analyzed data from 2012–2016, incidence rates have increased by 2.2% annually among those age < 50 years and decreased by 3.3% annually in those age 65 and older. The increase in *early-onset CRC* (younger than 50 years old) is characterized by more distal colon and rectal tumors and is evenly distributed between men and women. Germline variants are identified in approximately 15% of patients with early-onset CRC, of whom half have Lynch syndrome with MMR gene pathogenic variants; thus, 85% of early-onset CRC is considered to be sporadic. In the United States, the incidence of early-onset CRC is rising in all racial and ethnic groups. It is highest in Black adults, but the incidence is rising most quickly in non-Hispanic White adults. Epidemiologic studies suggest that the increase in sporadic (nonhereditary) early-onset CRC may be related to dietary changes (increased consumption of refined grains, red meats, and processed sugars), alcohol consumption, changes in the gut microbiome, sedentary lifestyle, obesity, and metabolic syndrome. It is estimated that by 2030, 10% of colon cancers and 20% of rectal cancers will occur in patients under age 50 years.

B. Family History of Neoplasia

A family history of CRC is present in approximately 20% of patients with colon cancer. Hereditary factors are believed to contribute to 20–30% of CRCs; however, the genes responsible for many of these cases have not yet been identified. Hereditary cancer syndromes (Lynch syndrome, polyposis syndromes, and other germline mutations) account for approximately 3–4% of CRC in patients 50 years or older but 15–20% of patients with early-onset CRC (see Chapter 17).

Lynch syndrome is the most common hereditary cancer syndrome responsible for CRC. Lynch syndrome is caused by pathogenic germline variants in one of four DNA mismatch repair genes or by a deletion in the *EPCAM* gene.

Approximately 6% of the Ashkenazi Jewish population has a missense pathologic variant in the *APC* gene *(APC I1307K)* that confers a modestly increased lifetime risk of developing CRC (OR 1.4–1.9) that phenotypically resembles sporadic CRC rather than familial adenomatous polyposis. Genetic screening is available, and patients harboring a variant in the *APC* gene merit more intensive colorectal screening.

A family history of CRC or adenomatous polyps is one of the most important risk factors for CRC. The risk of colon cancer is proportionate to the number and age of affected first-degree family members with colon neoplasia. Individuals with one first-degree family member diagnosed with CRC at age < 60 or two first-degree members diagnosed at any age have up to a 20% lifetime risk of developing CRC. First-degree relatives of patients with adenomatous polyps also have a twofold increased risk for colorectal neoplasia, especially if they were younger than 60 years when the polyp was detected or if the polyp was 10 mm or larger.

C. Inflammatory Bowel Disease

The risk of adenocarcinoma of the colon begins to rise 8 years after disease onset in patients with ulcerative colitis and Crohn colitis (see Chapter 17). For this reason, *initiation of surveillance with colonoscopy is recommended at 8–10 years after onset of IBD symptoms*.

D. Dietary and Lifestyle Factors and Chemoprevention

In epidemiologic studies, diets rich in fats and red meat are associated with an increased risk of colorectal adenomas and cancer, whereas diets high in fruits, vegetables, and fiber are associated with a decreased risk. However, prospective studies have *not* shown a reduction in colon cancer or recurrence of adenomatous polyps with diets that are low in fat; that are high in fiber, fruits, or vegetables; or that include calcium, folate, β-carotene, or vitamin A, C, D, or E supplements.

Meta-analyses suggest that individuals with increased physical activity are up to 27% less likely to develop colon cancer. There also is a correlation between increasing BMI and cancer risk, such that for each increase of 5 in BMI, there is a 5% increased cancer risk. Patients with higher levels of pre- and post-diagnosis physical activity experience reduced CRC-specific mortality and all-cause mortality. Maintaining a healthy body weight, a healthy diet, and a physically active lifestyle are recommended in CRC survivors.

E. Other Factors

The overall incidence of CRC is similar in men and women; however, similar incidence rates are reached in women about 4–6 years later than in men. A higher proportion of cancers are located in the proximal colon in women (46%) than men (37%). The incidence and mortality of colon adenocarcinoma are higher in Black and Native American persons than in White persons. It is unclear whether this is due to genetic or socioeconomic factors (eg, diet or reduced access to medical care).

Clinical Findings

A. Symptoms and Signs

Adenocarcinomas grow slowly and may be present for several years before symptoms appear. Many asymptomatic tumors may be detected by the presence of *fecal occult blood* (see Screening for Colorectal Neoplasms, below). Symptoms depend on the location of the carcinoma. Chronic blood loss from right-sided colonic cancers may cause iron deficiency anemia, manifested by fatigue and weakness. Obstruction, however, is uncommon because of the large diameter of the right colon and the liquid consistency of the fecal material. Lesions of the left colon often involve the bowel circumferentially. Because the left colon has a smaller diameter, and the fecal matter is solid, obstructive symptoms may develop with colicky abdominal pain and a change in bowel habits. Constipation may alternate with periods of increased frequency and loose stools. The stool may be streaked with blood, though marked bleeding is unusual. With rectal cancers, patients note tenesmus, urgency, and recurrent hematochezia. Physical examination is usually normal except in advanced disease. The liver should be examined for hepatomegaly, suggesting metastatic spread. For cancers of the distal rectum, digital examination is necessary to determine whether there is extension into the anal sphincter or fixation, suggesting extension to the pelvic floor.

B. Laboratory Findings

A CBC should be obtained to look for anemia. Elevated liver biochemical tests, particularly the serum alkaline phosphatase, raise suspicion of metastatic disease. The *serum carcinoembryonic antigen (CEA)* should be measured in all patients with proven CRC but is not appropriate for screening. The CEA is not elevated in many patients with confirmed CRC; conversely, the CEA may be elevated in active smokers and those with a variety of other nonmalignant conditions. That said, a preoperative CEA level > 5 ng/mL is a poor prognostic indicator. After complete surgical resection, CEA levels should normalize; persistently elevated levels suggest the presence of persistent disease and warrant further evaluation. CEA is routinely monitored at the time of adjuvant therapy and during postoperative surveillance for patients who had elevated levels before resection.

C. Colonoscopy

Colonoscopy is the required diagnostic procedure in patients with a clinical history suggestive of CRC or in patients with an abnormality suspicious for cancer detected on radiographic imaging. Colonoscopy and upper endoscopy should be considered in all adults with new-onset iron deficiency anemia. Colonoscopy permits biopsy for pathologic confirmation of malignancy. All new diagnoses of colorectal cancers should be evaluated for MMR/MSI status.

D. Imaging

Chest, abdominal, and pelvic CT scans with intravenous contrast are required for preoperative staging of CRC. CT scans may demonstrate distant metastases but are less accurate in the determination of the level of local tumor extension (T stage) or lymphatic spread (N stage). Intraoperative assessment of the liver by direct palpation and ultrasonography can be performed to detect hepatic metastases (M stage). For **rectal cancers** (generally defined as tumors arising 12 cm or less proximal to the anal verge), pelvic MRI or endorectal ultrasonography is required to determine the depth of penetration of the cancer through the rectal wall (T stage) and perirectal lymph nodes (N stage), informing decisions about preoperative (neoadjuvant) chemoradiotherapy and operative management.

PET (with or without CT) is *not* routinely used for staging or surveillance since many CRCs are not highly PET avid and liver metastases may be inapparent amid high background liver activity.

Staging

The TNM system is the commonly used classification to stage CRC. Staging correlates with the patient's long-term survival and is used to determine which patients should receive neoadjuvant or adjuvant therapy.

Differential Diagnosis

The nonspecific symptoms of CRC may be confused with those of irritable bowel syndrome, diverticular disease, ischemic colitis, IBD, infectious colitis, and hemorrhoids. Neoplasm must be excluded in any patient who reports a change in bowel habits or hematochezia or who has an unexplained iron deficiency anemia or occult blood in stool samples.

Treatment

A. Colon Cancer

Surgical resection of the colonic tumor is the treatment of choice for almost all patients. It may be curative in patients with stage I, II, and III disease and even some patients with metastatic (stage IV) disease. Multiple studies demonstrate that minimally invasive, laparoscopically assisted colectomy results in similar outcomes and rates of recurrence to open colectomy. Regional dissection of at least 12 lymph nodes should be performed to determine staging, which guides decisions about adjuvant therapy. Following complete endoscopic removal of an adenomatous polyp (polypectomy) that is found on pathologic review to contain a focus of cancer invasion into the submucosa (T1 disease; "malignant polyp"), observation is a reasonable alternative to further surgical resection in carefully selected patients. Pathology review of CRCs should include testing for mismatch repair proteins for all patients. Tumors of patients with metastatic CRC should also be sent for comprehensive molecular profiling to include *KRAS*, *NRAS*, *BRAF*, and *HER2*.

Following surgical resection, chemotherapy has been demonstrated to improve overall and tumor-free survival in select patients with colon cancer depending on stage (Table 44–2).

1. Stage I—Because of the excellent 5-year survival rate (approximately 92%), no adjuvant therapy is recommended for stage I colon cancer.

2. Stage II (node-negative disease)—The 5-year survival rate is approximately 87% for stage IIA disease and 63% for stage IIB disease. A significant survival benefit from adjuvant chemotherapy has not been demonstrated in most RCTs for stage II colon cancer (see discussion for stage III disease). However, otherwise healthy patients with stage II disease who are at higher risk for recurrence (perforation; obstruction; close or indeterminate margins; poorly differentiated histology; lymphatic, vascular, or perineural invasion; T4 tumors; or < 12 lymph nodes sampled) may benefit from adjuvant chemotherapy. Patients whose tumors reveal MSI have a more favorable prognosis and do not benefit from 5-fluorouracil-based adjuvant therapy.

3. Stage III (node-positive disease)—With surgical resection alone, the expected 5-year survival rate is 30–50%. Postoperative adjuvant chemotherapy significantly increases disease-free survival as well as overall survival by up to 30% and is recommended for all fit patients (Table 44–2). Multiple large, well-designed studies of adjuvant therapy for stage III CRC have reported a higher rate of disease-free survival at 5 years for patients treated for 6 months postoperatively with a combination of oxaliplatin, 5-fluorouracil, and leucovorin (FOLFOX) (73.3%) than with 5-fluorouracil and leucovorin (FL) alone (67.4%). Similar benefit was reported for patients treated with oxaliplatin and capecitabine (orally active fluoropyrimidine). A large international RCT comparing 3 months with 6 months of adjuvant therapy for colon cancer found that 3 months of adjuvant therapy resulted in equivalent disease-free survival for patients with earlier stage T1, T2, or T3, and N1 disease but not with more advanced T4 or N2 disease. For patients with high-risk disease (T4 or N2), 6 months of adjuvant chemotherapy are still recommended. The addition of a biologic agent (bevacizumab or cetuximab) to adjuvant chemotherapy does not improve outcomes.

4. Stage IV (metastatic disease)—Approximately 20% of patients have metastatic disease at the time of initial diagnosis, and another 25–30% eventually develop metastasis. In the absence of cancer-directed treatment, the median survival is < 12 months; however, with effective therapy, median survival approaches 30 months.

A subset of patients with metastatic disease has limited disease that is potentially curable with surgical resection. Resection of isolated liver metastases may result in long-term (over 5 years) survival in 35–55% of cases. A subset of patients who have isolated pulmonary metastases may undergo resection (or radiation) with potential cure. Surgery may also be warranted to provide palliation of tumor bleeding or obstruction.

Beyond surgical resection, radiation, and local ablative techniques for limited disease, the primary treatment for unresectable metastatic CRC is systemic therapy (cytotoxic chemotherapy, biologic therapy [eg, antibodies to cellular growth factors], immunotherapy, and combinations of these therapies). The goals of systemic therapy for patients with metastatic CRC are to slow tumor progression while maintaining a reasonable quality of life for as long as possible. Tailoring treatment to the pathologic and molecular features of the cancer improves overall survival.

Two cytotoxic chemotherapeutic regimens—FOLFOX (the addition of oxaliplatin to 5-fluorouracil and folinic acid) or FOLFIRI (the addition of irinotecan to 5-fluorouracil and folinic acid)—are the preferred first-line treatments for fit patients. For convenience, oral capecitabine (instead of intravenous 5-fluorouracil and leucovorin) can be used in combination with oxaliplatin since it has similar efficacy to 5-fluorouracil; however, combination with irinotecan is not recommended due to increased toxicity (diarrhea).

Addition of biologic therapy to combination chemotherapy improves response rates and overall survival and is recommended in the first line of treatment in suitable patients. Genomic profiling to detect genetic variants identifies the treatments that may be most effective. For patients with left-sided metastatic CRC who have *KRAS/NRAS/BRAF* wild-type tumors, cetuximab and panitumumab (monoclonal antibodies to the epithelial growth factor receptor [EGFR]), in combination with chemotherapy, can extend median survival by 2 to 4 months compared with chemotherapy alone.

For the 3–5% of patients with MSI or dMMR, immunotherapy may be used in first or subsequent line therapy; it has improved treatment outcomes compared to cytotoxic chemotherapy with a median overall survival of 31.4 months in previously treated patients. Patients without a targetable sequence variation, or who have progressed on a targeted agent may be candidates for bevacizumab, a monoclonal antibody targeting VEGF. Combination of bevacizumab with FOLFOX or FOLFIRI prolongs mean survival by 2–5 months compared with either regimen alone.

When disease progresses despite treatment either with FOLFOX or with FOLFIRI (often in conjunction with bevacizumab or an EGFR-targeted antibody), therapy may be switched to the alternate regimen.

Clinical trial participation should be considered for eligible patients who are intolerant of or ineligible for standard therapies or in whom disease has progressed.

Because the list of potentially actionable pathogenic genetic variants continues to grow, extended molecular testing with a next-generation sequencing panel should be considered in all new diagnoses of metastatic CRC.

B. Rectal Cancer

The treatment approach to rectal cancer is guided by clinical staging as determined by colonoscopy and endorectal ultrasound or rectal MRI. In carefully selected patients with small (< 4 cm), mobile, well-differentiated T1 rectal cancers that are < 8 cm from the anal verge, transanal endoscopic or surgical excision may be considered. All other patients with rectal cancer require either a low anterior resection with a colorectal anastomosis or an abdominoperineal resection with a colostomy, depending on how far above the anal verge the cancer is located and the extent of local tumor spread.

For invasive rectal carcinoma, the combination of preoperative chemoradiation and preoperative chemotherapy ("total neoadjuvant therapy") is generally recommended in all node-positive tumors and in T3 and greater tumors due to increased risk of local recurrence. Total neoadjuvant therapy has become the preferred standard in most centers because chemotherapy is more tolerable prior to surgery, leads to improved local control, and may result in improved long-term survival. Additionally, it provides the opportunity for pathologic assessment of treatment response and for low rectal tumors the potential to convert to a colostomy-sparing surgery. For patients with a low rectal tumor (in whom resection would require a permanent colostomy), nonoperative therapy with close surveillance by endoscopy and cross-sectional imaging may be considered in those who have had a complete clinical response to total neoadjuvant therapy. Patients wishing to pursue this should be counseled on the potential for recurrence and the necessity of close follow-up.

After neoadjuvant therapy, the operative approach (low anterior resection versus abdominoperineal resection with colostomy) depends on how far above the anal verge the cancer is located, its size and depth of penetration, and the patient's overall condition. Careful dissection of the entire mesorectum by either open or laparoscopic surgery reduces local recurrence to 5%. Although low anterior resections obviate a colostomy, they are associated with increased immediate postsurgical complications (eg, leak, dehiscence, stricture) and long-term defecatory complaints (eg, increased stool frequency, and incontinence). With unresectable rectal cancer, the patient may be palliated with a diverting colostomy.

▶ Follow-Up After Surgery

Patients with CRC who have undergone resections for cure are monitored closely to look for evidence of symptomatic or asymptomatic tumor recurrence that may occasionally be amenable to curative resection. Patients should be evaluated every 3–6 months for 2 years and then every 6 months for a total of 5 years with history, physical examination, and laboratory surveillance, including serum CEA levels if baseline levels are elevated. The NCCN and American Society of Clinical Oncology guidelines recommend surveillance contrast CT scans of chest, abdomen, and pelvis up to every 6–12 months for up to 5 years post-resection in high-risk stage II and all stage III patients. Patients who had a complete preoperative colonoscopy should undergo another colonoscopy 1 year after surgical resection. Patients who did not undergo full colonoscopy preoperatively should undergo a full colonoscopy after completion of all adjuvant therapy to exclude other synchronous colorectal neoplasms. If a colonoscopy does not detect new adenomatous polyps 1 year postoperatively, surveillance colonoscopy should be performed every 3–5 years thereafter to look for metachronous polyps or cancer. Most CRC recurrences occur within 3 years of the conclusion of treatment, and almost all (> 90%) occur within 5 years.

▶ Prognosis

The stage of disease at presentation remains the most important determinant of 5-year survival in CRC, which is estimated in older registries as: stage I, > 90%; stage II, 70–85%; stage III with fewer than four positive lymph nodes, 67%; stage III with more than four positive lymph nodes, 33%; and stage IV, 5–7%. Long-term registry follow-up data from the modern chemotherapy era are not yet available. For each stage, rectal cancers have a worse prognosis. For those patients whose disease progresses despite therapy, meticulous efforts at palliative care are essential (see Chapter 5).

Screening for Colorectal Neoplasms

CRC is ideal for screening because it is a common disease that is fatal in almost 50% of cases and yet is curable if detected at an earlier stage. Furthermore, *most cases arise from benign adenomatous or serrated polyps that progress over many years to cancer, and removal of these polyps has been shown to prevent the majority of cancers*. CRC screening is endorsed by the USPSTF, the ACS, the NCCN, and every professional gastroenterology and colorectal surgery society. Although there is continued debate about the optimal cost-effective means of providing population screening, there is now almost unanimous consent that screening of some kind should be offered to all adults ages 45–75 years. The 2018 ACS and 2021 USPSTF recommendations for screening are listed in Table 44–12. *Due to a rising incidence of CRC in adults younger than 50 years, the 2021 American College of Gastroenterology (ACG), 2021 USPSTF, 2018 ACS, and 2022 US Multi-society Task Force guidelines all endorse consideration of screening in asymptomatic, average-risk adults beginning at age 45 years, and at younger ages for high-risk adults (such as those with a history of IBD or primary sclerosing cholangitis, or those with a family history of a first-degree relative with colorectal neoplasia [Table 44–12]).*

Table 44–12. Recommendations for colorectal cancer screening,[1] based on 2021 USPSTF and 2018 American Cancer Society recommendations.[2]

Average-risk individuals aged ≥ 45 years[2]
- Annual fecal occult blood testing using higher sensitivity tests (Hemoccult SENSA)
- Annual fecal immunochemical test (FIT)
- Fecal DNA test (with FIT every 1–3 years)
- Flexible sigmoidoscopy every 5 years
- Colonoscopy every 10 years
- CT colonography every 5 years

Individuals with a family history of a first-degree relative with colorectal neoplasia
- **Single first-degree relative with colorectal cancer diagnosed at age 60 years or older:** Begin screening at age 40 years. Screening guidelines same as average-risk individual; however, preferred method is colonoscopy every 10 years.
- **Single first-degree relative with colorectal cancer or advanced adenoma diagnosed before age 60 years, or two first-degree relatives:** Begin screening at age 40 years or at age 10 years younger than age at diagnosis of the youngest affected relative, whichever is first in time. Recommended screening: colonoscopy every 5 years.

[1] For recommendations for families with inherited polyposis syndromes or hereditary nonpolyposis colon cancer, see Chapter 17.

[2] The USPSTF and American Cancer Society recommend screening of average-risk adults aged 45–75 years and screening of selected patients aged 76–85 years based on overall health, life expectancy, patient preferences, and prior screening results.

The potential for harm from screening must be weighed against the likelihood of benefit, especially in older patients with comorbid illnesses and shorter life expectancy. Although routine screening is not recommended in adults above age 75 years, it may be considered on a case-by-case basis in adults aged 76–85 years, taking into account the patient's overall health and functional status and their prior screening history.

Patients with first-degree relatives with colorectal neoplasms (cancer or adenomatous polyps) are at increased risk. Therefore, most guidelines recommend initiating screening at age 40–50 years (or 10 years younger than the familial diagnosis) in individuals with first-degree relatives with CRC or with advanced adenomas. Recommendations for screening in families with inherited cancer syndromes or IBD are provided in Chapter 17.

Screening tests may be classified into two broad categories: *stool-based tests* and *examinations that visualize the structure of the colon* by direct endoscopic inspection or radiographic imaging. The advantages and disadvantages of available tests are summarized below and should be discussed with patients prior to study selection. The US Multi-society Task Force and the 2021 ACG guidelines endorse the fecal immunochemical testing (FIT) and colonoscopy as the preferred stool-based and imaging-based screening modalities, respectively. However, the "best" test may be that which the patient agrees to do and then completes. Compliance with recommended testing can be increased significantly using a combination of automated reminders and personal outreach by health care providers.

A. Stool-Based Tests

1. Fecal occult blood test—Most CRCs and some large adenomas result in increased chronic blood loss. A variety of tests for fecal occult blood are commercially available that have varying sensitivities and specificities for colorectal neoplasia. These include *guaiac-based fecal occult blood testing (gFOBT)* (eg, Hemoccult SENSA) that detects the pseudoperoxidase activity of heme or hemoglobin and *testing that detects human globin (FIT)*. In clinical trials, FIT has proven superior to gFOBT in sensitivity for detection of CRC and advanced adenomas with similar specificity.

Because FIT is not affected by diet or medications and has superior accuracy, its use is preferred by many health care plans instead of gFOBT. FIT is also a suitable option for patients seeking a noninvasive screening test who are willing to undertake annual fecal testing. Patients with a positive FIT test must undergo further evaluation with colonoscopy. In 14 clinical studies (n = 45,403), the pooled sensitivity and specificity of FIT for CRC in average-risk patients were 74% and 94%, respectively. FIT testing is also the preferred option for population-based screening in various European and Australian programs. For optimal neoplasia detection, FIT testing should be performed annually.

2. Multitarget stool DNA assay—*Stool DNA panel testing* measures gene variants and methylated gene markers from exfoliated tumor cells. Multitarget stool DNA testing (mt-sDNA) combines a fecal DNA panel with a FIT. In the United States, two commercially available mt-sDNA test (Cologuard and Cologuard Plus) are approved for colorectal screening in average-risk persons. Compared with other tests, the mt-sDNA tests are more expensive and require collection, preparation, and mailing of an entire stool specimen.

In a prospective comparative trial conducted in persons at average risk for CRC undergoing colonoscopy, the sensitivity for CRC for Cologuard was 92.3% versus 73.8% for FIT alone and the sensitivity for adenomas larger than 1 cm or serrated polyps for Cologuard was 42.4% versus 23.8% for FIT alone. Repeat testing is recommended in 3 years for persons with a negative test. A positive stool DNA panel test requires colonoscopy evaluation.

In 2024, the FDA approved a "next-generation" multitarget stool DNA test (Cologuard Plus) for patients at average risk for CRC. In a randomized prospective study of asymptomatic adults undergoing colonoscopy, the next-generation test had higher sensitivity than FIT for CRC (93.9% versus 67.3%) and advanced precancerous lesions (43.4% versus 23.3%) but lower specificity for advanced precancerous lesions (90.6% versus 94.8%).

B. Endoscopic Examinations of the Colon

1. Colonoscopy—Colonoscopy permits examination of the entire colon. In addition to detecting early cancers, colonoscopy allows removal of adenomatous polyps by biopsy or polypectomy, which is believed to reduce the risk of subsequent cancer. Over the past decade, there has been a dramatic increase in screening colonoscopy, with over 60% of US adults screened in the past 10 years. In asymptomatic individuals between 50 and 75 years of age undergoing screening colonoscopy, the prevalence of advanced colonic neoplasia is 4–11% and of colon cancer is 0.1–1%.

Although colonoscopy is believed to be the most sensitive test for detecting adenomas and cancer, it has several disadvantages. Adequate visualization of the entire colonic mucosa requires thorough bowel cleansing the evening and morning prior to the examination. To alleviate discomfort during the procedure, intravenous sedation is used for most patients, necessitating a companion to transport the patient home post-procedure. Serious complications occur uncommonly; they include perforation (0.1%), bleeding (0.25%), and death (2.9/100,000).

The skill of the operator has a major impact upon the quality of the colonoscopy examination. In several studies, the rate of CRC within 3 years of a screening colonoscopy was 0.7–0.9%, ie, approximately 1 in 110 patients. Population-based case-control and cohort studies suggest that colonoscopy is associated with greater reduction in CRC incidence and mortality in the distal colon (80%) than the proximal colon (40–60%). This may be attributable to incomplete examination of the proximal colon, and differences between the proximal and distal colon that include worse bowel preparation, suboptimal colonoscopic technique, and a higher prevalence of serrated polyps and flat adenomas, which are more difficult to identify than raised (sessile or pedunculated) polyps. To optimize diagnostic accuracy as well as patient safety and comfort, colonoscopy should be performed after optimal bowel preparation by a well-trained endoscopist who spends sufficient time (at least 7–9 minutes) carefully examining the colon (especially the proximal colon) while withdrawing the endoscope.

2. Flexible sigmoidoscopy—Use of a 60-cm flexible sigmoidoscope permits visualization of the rectosigmoid and descending colon. Patients with an adenomatous polyp of any size found during screening sigmoidoscopy should subsequently undergo colonoscopy to evaluate the proximal colon. In four RCTs, intention to screen with 1- or 2-time flexible sigmoidoscopy versus no screening was associated with a significant decrease in CRC-specific mortality.

The chief disadvantage of screening with flexible sigmoidoscopy is that it requires some bowel cleansing, it may be associated with some discomfort (since intravenous sedation is not used), and it does not examine the proximal colon. The prevalence of proximal versus distal neoplasia is higher in persons older than age 65 years, in Black adults, and in women.

C. Radiographic and Other Imaging of the Colon

1. CT colonography—CT colonography requires a similar bowel cleansing regimen as colonoscopy as well as insufflation of air into the colon through a rectal tube, which may be associated with discomfort.

Using imaging software with multidetector helical scanners, the sensitivity is > 95% for the detection of cancer and 86% for the detection of adenomatous polyps 6 mm or larger. CT colonography is less sensitive than colonoscopy for the detection of flat adenomas and serrated polyps.

The chief disadvantages of CT colonography are the need for a bowel preparation, limited availability in many health care systems, potential harms resulting from (repeated) low-dose ionizing radiation exposure, and the potential for finding incidental extracolonic findings that may lead to further evaluations. CT colonography is an excellent screening option in patients who do not wish to undergo or are unsuitable for colonoscopy and in patients in whom colonoscopy could not be completed.

2. Capsule colonoscopy—Imaging of the colon can be accomplished by oral ingestion of a capsule that captures video images of the colon. Compared with colonoscopy, the colon capsule has reduced sensitivity for polyps > 6 mm (64% versus 84%) and for CRCs (74% versus 100%). At present, it is approved by the FDA for evaluation in patients who are not suitable candidates for colonoscopy or in whom colonoscopy could not evaluate the proximal colon. In addition to its suboptimal sensitivity for neoplasia, the main disadvantages of capsule colonoscopy are its cost, need for extensive bowel preparation, varying reimbursement by insurance carriers, and small risk of small bowel obstruction.

When to Refer

- Patients with symptoms (change in bowel habits, hematochezia), signs (mass on abdominal examination or digital rectal examination [DRE]), or laboratory tests (iron deficiency anemia) suggestive of colorectal neoplasia should be referred for colonoscopy.
- Patients with suspected CRC or adenomatous polyps of any size should be referred for colonoscopy.
- Virtually all patients with proven CRC should be referred to a surgeon for resection. Patients with clinical stage T3 or node-positive rectal tumors (or both) also should be referred to medical and radiation oncologists preoperatively for neoadjuvant therapy. Patients with stage II, III, or IV colorectal tumors should be referred to a medical oncologist.

When to Admit

- Patients with complications of CRC (eg, obstruction, acute bleeding) requiring urgent evaluation and intervention.
- Patients with advanced metastatic disease requiring palliative care.

CARCINOMA OF THE ANUS

Cancers arising from the mucosa of the anal canal are relatively rare, comprising only 2% of all GI malignancies. However, the incidence is increasing by about 2.7% per year. Anal carcinoma occurred in approximately 10,540 patients in the United States in 2024, more commonly in women than men (2:1 ratio). *Squamous cell carcinomas* (SCC) make up the majority of anal cancers; *adenocarcinomas* are uncommon.

Over 90% of anal cancers are associated with HPV infections (most commonly, HPV-16 and -18). Anal cancer is increased among women with HPV-associated cervical, vulvar, or vaginal squamous intraepithelial lesions (CIN grade 3) or cancer, among men who are having sex with men, and among women and men who have HIV or have received a solid organ transplant.

Identification and screening of high-risk individuals with HPV testing and anal cytology facilitate detection of anal low- and high-grade squamous intraepithelial lesions (LSIL and HSIL, respectively) and early-stage cancers. Anoscopy (preferably high-resolution) with biopsy is warranted in patients with positive cytology. Early detection and treatment of HSIL with either topical treatment or surgical ablation may reduce progression to advanced cancer. In a 2022 phase 3 RCT of HIV-infected patients with anal HSIL, treatment with office ablation, excision, or topical therapies resulted in a lowering of progression to anal cancer at 48 months by 57% compared with those actively monitored without treatment.

The most common symptoms of anal carcinoma are bleeding, pain, and local mass. The lesion is often confused with hemorrhoids or other common anal disorders. These tumors tend to become annular, invade the sphincter, and spread upward via the lymphatics into the perirectal mesenteric lymphatic nodes. CT or MRI scans of the abdomen and pelvis and chest CT are required to identify regional lymphadenopathy or metastatic disease at diagnosis; PET imaging may be used in conjunction.

Treatment depends on the tumor location, histology, and stage. Well-differentiated and small (< 2 cm) superficial lesions of the perianal skin may be treated with wide local excision.

The more common squamous cell carcinoma of the anal canal as well as large perianal tumors invading the sphincter or rectum are treated with combined-modality external radiation with simultaneous chemotherapy (5-fluorouracil or capecitabine plus mitomycin). Local control is achieved in approximately 80% of patients. Radical surgery (abdominoperineal resection) is reserved for patients who fail chemotherapy and radiation therapy.

The 5-year survival rate is 81% for localized tumors and 30% for metastatic disease. The combination of carboplatin and paclitaxel is the most commonly used regimen for the first-line treatment of metastatic anal squamous cell carcinoma. Checkpoint inhibitor therapy should be strongly considered in the second-line setting in all patients with good performance status.

Treatment of anal adenocarcinoma is like that of rectal adenocarcinoma (see above), typically by trimodality therapy with chemoradiotherapy, chemotherapy, and abdominoperineal resection.

GASTROENTEROPANCREATIC NEUROENDOCRINE TUMORS (GEP-NETS)

ESSENTIALS OF DIAGNOSIS

- GEP-NETs are neuroendocrine tumors that originate in the GI tract, lungs, or pancreas.
- About 60% of GEP-NETs are nonsecretory or secretory without clinical manifestations; they may be detected incidentally or may present with weight loss, abdominal pain, or jaundice.
- Functioning pancreatic NETs (islet cell tumors) may secrete insulin, glucagon, gastrin, somatostatin, cholecystokinin, or vasoactive intestinal polypeptide (VIP).
- Gastrointestinal NETs (also called "carcinoids") may arise from the esophagus, stomach, small intestine, colon, or lungs; functioning NETs may secrete serotonin or gastrin.

General Considerations

Gastroenteropancreatic neuroendocrine tumors (GEP-NETs) occur in the gastrointestinal tract (65%), lungs (20%), or pancreas (15%). About 20% of cases present with metastases with unknown primary location. According to the 2022 WHO pathology classification system, GEP-NET are divided into **well-differentiated neuroendocrine tumors (NETs)** and **poorly differentiated neuroendocrine carcinomas (NECs)**. NETs can be grade 1, 2, or 3 based on proliferative index, while NECs are by definition all high-grade. The treatment of NETs is entirely different than the treatment of NECs. The reported incidence of GEP-NETs is about 37 per million annually in the United States. About 40% are functional, producing hormones that may cause symptoms and also serve as tumor markers for diagnosis and follow-up. At presentation, 65% of GEP-NETs are unresectable or metastatic. Up to 25% of GEP-NETs are associated with one of four different inherited disorders: multiple endocrine neoplasia type 1 (MEN1), Von Hippel-Lindau (VHL), neurofibromatosis type 1, and tuberous sclerosis complex. In MEN1, GEP-NETs are usually gastrinomas, carcinoids, or nonfunctioning tumors and are a common cause of death. In VHL, GEP-NETs are usually multiple and benign.

1. Gastrointestinal tract NETs (GI-NETS)—Frequently called "carcinoids," GI-NETs occur most commonly in the small intestine (45%), rectum (20%), appendix (17%), colon (11%), and stomach (< 10%). GI-NETs may secrete serotonin, gastrin, or substance P. Most GI-NETs express somatostatin receptors, which aids in diagnostic studies. Multiple carcinoids are observed in about 28% of cases. Although tumors are usually indolent, metastases are common, particularly to the liver, lymph nodes, and peritoneum. Well-differentiated GI-NETs may (but often do not) secrete a variety of hormones, including serotonin, somatostatin, gastrin, and substance P. Gastrin-secreting NETs (**gastrinomas**) are discussed in Chapter 17 (see Zollinger-Ellison syndrome).

Gastric NETs (gNETs) make up < 1% of gastric neoplasms. They may occur sporadically or secondary to chronic hypergastrinemia that results in hyperplasia and transformation of enterochromaffin cells in the gastric fundus. They are classified into three types. **Type 1 gNETs** are associated with chronic atrophic gastritis, gastric achlorhydria, and consequent secondary hypergastrinemia. **Type 2 gNETs** are associated with Zollinger-Ellison syndrome caused by a gastrin-secreting NET (gastrinoma) most commonly located in the pancreas or duodenum. Although 75% of gastrinomas are sporadic, gNETs caused by gastrinomas occur almost exclusively in patients with MEN1. **Type 3 gNETs** are most often solitary and larger than 2 cm. They have a strong propensity for hepatic or pulmonary metastases and may be associated with carcinoid syndrome at initial presentation.

Small intestinal NETs most commonly arise in the distal ileum within 60 cm of the ileocecal valve. Jejunal-ileal NETs are the second most frequent location. The risk of metastatic spread increases when the tumor is 1 cm or larger and when it is larger than 2 cm with invasion beyond the muscularis propria.

Appendiceal NETs are identified in 0.3% of appendectomies, usually as an incidental finding. Almost 80% of these tumors are smaller than 1 cm, and 90% are smaller than 2 cm. However, in patients with appendiceal NETs larger than 2 cm, approximately 90% develop nodal and distant metastases; therefore, right hemicolectomy is recommended in these cases.

Rectal NETs are usually detected incidentally as submucosal nodules during proctoscopic examination and often locally excised by biopsy or snare polypectomy before the histologic diagnosis is known. Rectal NETs smaller than 1 cm virtually never metastasize and are treated effectively with local endoscopic or transanal excision. Larger tumors are associated with the development of metastasis in 10%. Hence, a more extensive cancer resection operation is warranted in otherwise healthy patients with rectal NETs larger than 1–2 cm or with high-risk features (such as invasion of muscularis propria or evidence of nodal involvement) or both.

2. Pancreatic NETs (pNETs)—Well-differentiated pancreatic NETs (pNETs) arise from islet cells and may (but often do not) secrete a variety of hormones, including gastrin, insulin, glucagon, somatostatin, and VIP. Nonfunctional pNETs produce no significant hormones and usually grow to large size prior to detection. They may secrete CgA or pancreatic polypeptide, which can be used as tumor markers.

Insulinomas are the most common functional type of pNET and are usually small, intrapancreatic, and benign (90%). Insulinomas are solitary in 95% of sporadic cases but are multiple in about 90% of cases arising in MEN 1 (see Chapter 28).

Gastrinomas are often malignant (about 50%) and metastasize to the liver. Gastrinomas are typically found in the duodenum (49%), pancreas (24%), or lymph nodes (11%). Sporadic gastrinoma is rarely suspected at the onset of symptoms; typically, there is an average of a 5-year delay in diagnosis. About 22% of gastrinomas arise in patients with MEN 1, who usually present at a younger age, often with multiple tumors; hyperparathyroidism can occur many years before or after the discovery of a gastrinoma (see Chapter 17, Zollinger-Ellison syndrome).

Glucagonomas are rare and usually malignant, despite their benign histologic appearance. They usually arise as a large intrapancreatic tumor with 60% having liver metastases apparent by the time of diagnosis. Besides glucagon, they usually secrete additional hormones, including gastrin.

Somatostatinomas are very rare and usually single. They arise in the pancreas (50%) or small intestine. They secrete somatostatin.

VIPomas are quite rare and are usually a single intrapancreatic tumor with metastases usually evident (80%) at diagnosis. They produce VIP.

Cholecystokinin-producing tumors (CCKomas) are rare tumors of the endocrine pancreas.

Clinical Findings

A. Symptoms and Signs

Most **GI-NETs** < 1–2 cm are asymptomatic but difficult to detect by endoscopy or imaging studies. The risk of metastatic spread increases when the tumor is 1 cm or larger and when it is > 2 cm with invasion beyond the muscularis propria. Symptomatic GI-NETs typically present with abdominal pain, weight loss, intestinal obstruction, intestinal bleeding, bowel infarction, or jaundice due to hepatic metastases. Small intestinal NETs most commonly arise in the distal ileum within 60 cm of the ileocecal valve. Jejunal-ileal NETs are the second most frequent location. Appendiceal and rectal NETs usually are small and asymptomatic, but large lesions can cause bleeding, obstruction, or altered bowel habits.

Carcinoid syndrome, which occurs in < 10% of patients with GI-NETs, is caused by tumor secretion of hormonal mediators, including serotonin. Manifestations include facial flushing, abdominal cramps and diarrhea, bronchospasm, cardiac lesions (pulmonary or tricuspid stenosis or regurgitation in 10–30%), and telangiectasias. Dry skin and flushing typically affect the upper chest, neck, and face and can last from 30 seconds to 30 minutes, although flushing with bronchial carcinoids can persist for days. Flushing can be unprovoked or precipitated by exercise, anesthesia, emotional stimuli, or foods (eg, bananas, tomatoes, cheese, kiwi, eggplant, and alcohol). Tumor-induced fibrosis can also occur in the retroperitoneum, causing ureteral obstruction or Peyronie disease. Pellagra (glossitis, confusion, dry skin) from niacin deficiency may occur in patients with a heavy tumor burden. *More than 90% of patients with carcinoid syndrome have hepatic metastases, usually from NETs of small bowel origin.*

Foregut carcinoids secrete serotonin that is hepatically metabolized and therefore produce carcinoid syndrome only when they have metastasized to the liver. Ileal carcinoids often present with intestinal obstruction or intestinal bleeding. Hindgut carcinoids rarely produce serotonin and do not cause carcinoid syndrome. Bronchial carcinoids secrete serotonin and can produce carcinoid syndrome even without hepatic metastases.

Pancreatic pNETs may present with symptoms caused by local growth of the pancreatic tumor or hepatic metastases, including abdominal pain, vomiting, upper GI obstruction, jaundice, or hepatomegaly. Functioning pNETs may produce symptoms due to the hormones secreted. Insulinomas secreted may present with the symptoms of fasting hypoglycemia (see Chapter 29). Gastrinomas may be asymptomatic but usually present with manifestations of gastric acid hypersecretion (Zollinger-Ellison syndrome), including peptic ulcer disease and esophagitis. Symptoms include abdominal pain (75%), heartburn (44%), bleeding (25%), diarrhea, and weight loss (17%). About 75% of gastrinomas are sporadic, while 25% are multiple and occur with MEN type 1. More than 50% of gastrinomas are malignant and metastasize to lymph nodes and liver. (See Zollinger-Ellison syndrome in Chapter 17.)

Glucagonomas usually present with weight loss caused by glucagon-stimulated protein hepatic gluconeogenesis and related protein catabolism. Other common manifestations include diarrhea, nausea, peptic ulcer, hypoaminoacidemia, or necrolytic migratory erythema, known as "glucagonoma syndrome." Diabetes mellitus develops in about 35% of patients.

Somatostatinomas can present with a classic symptom triad: diabetes mellitus due to its inhibition of insulin and glucagon secretion, cholelithiasis due to its inhibition of gallbladder motility, and steatorrhea due to inhibition of pancreatic exocrine function. Diarrhea, hypochlorhydria, and anemia can also occur.

VIPomas present with profuse *w*atery *d*iarrhea (unremitting), *h*ypokalemia, and *a*chlorhydria ("WDHA"), the so-called *Verner-Morrison syndrome*.

CCKomas may present with liver metastases and symptoms of diarrhea, peptic ulcer disease, and weight loss.

B. Laboratory Findings

Serum chromogranin A is elevated in most NETs. Although its sensitivity for small, localized tumors is unknown, serum chromogranin A is elevated in almost 90% of patients with advanced small bowel NETs. However, it should not be used as a diagnostic test. A variety of common medications, including PPIs, can cause falsely elevated serum chromogranin A levels. Although it is less sensitive than serum chromogranin A, the urinary 5-hydroxyindoleacetic acid (5-HIAA) level is also elevated in patients with metastatic GI-NETs and in carcinoid syndrome (symptomatic patients usually excrete > 25 mg of 5-HIAA per day in the urine). Because certain foods and medications can interfere with 5-HIAA levels, they should be withheld for 48 hours before the 24-hour urine collection.

For gNETs, initial diagnostic workup includes serum gastrin level (to distinguish types 1 and 2 from type 3), CBC, serum vitamin B12 level, and intrinsic factor antibody to diagnose pernicious anemia. For other GI-NETs (carcinoids) serum serotonin may be elevated along with urinary 5-hydroindoleacetic acid (5-HIAA).

For pancreatic NETs, functioning NETs are defined by the hormone secreted. Insulinomas produce insulin, proinsulin, and C-peptide. Gastrinomas secrete gastrin and CgA. Glucagonomas secrete glucagon and other hormones, including gastrin. CCKomas produce elevated serum levels of cholecystokinin and CgA.

C. Imaging

For gNETs, initial staging includes upper endoscopy and EUS. For other GI-NETs, abdominal CT or MRI may demonstrate a mesenteric mass with tethering of the bowel, lymphadenopathy, and hepatic metastasis. Most patients with carcinoid syndrome have liver metastasis on abdominal imaging. Localization of other GEP-NETs and their metastases is best done with PET scanning using ^{68}Ga-DOTATATE, a radiolabeled somatostatin analog. For localization of pancreatic insulinomas, preoperative localization studies have the following sensitivities: ultrasonography 25%, CT 25%, endoscopic ultrasonography 27%, transhepatic portal vein sampling 40%, and arteriography 45%. Nearly all insulinomas can be successfully located at surgery by the combination of intraoperative palpation (sensitivity 55%) and ultrasound (sensitivity 75%), and ^{68}Ga-DOTATATE-PET (sensitivity 90%).

Treatment

For types 1 and 2 gNETs, small lesions may be successfully treated with endoscopic resection followed by endoscopic surveillance. Patients with tumors > 2 cm with high-grade histology should undergo surgical resection (see Small Intestinal Adenocarcinomas section). Type 2 gNETs with underlying gastrinoma and Zollinger-Ellison syndrome may be treated with somatostatin analog (octreotide) therapy. Localized sporadic type 3 gNETs should be treated with partial or total gastrectomy and regional lymphadenectomy.

Surgery is the primary initial treatment for most other GEP-NETs and is a reasonable option even for patients with stage IV disease. The aggressiveness of the surgery may vary from conservative debulking to radical resection and even liver transplantation. However, incidentally discovered nonfunctioning pNETs that are asymptomatic and smaller than 2 cm often can be monitored without surgery. Small intestinal carcinoids generally are indolent tumors with slow spread. There is no proven role for adjuvant therapy after complete resection. Five-year survival rates for patients with stage I and II disease are 96% and 87%, respectively. In patients with resectable disease who have lymph node involvement (stage III), the 5-year survival rate is 74%; however, by 25 years, < 25% remain disease-free. Across stages, prognosis is strongly associated with histologic differentiation and grade. Patients with grade 1 disease may not require treatment for many years, even with metastatic disease. However, patients with grade 3 NETs may have a clinical course more like a NEC.

In patients with advanced disease, the decision to initiate therapy should be based on symptoms, burden of disease, rate of disease progression, and patient preference. Conventional cytotoxic chemotherapy agents do not achieve significant responses in NETs and have not been associated with improved outcomes. Tumor visualization of GEP-NETs on ^{64}Cu- or ^{68}Ga-DOTATATE-PET/CT imaging indicates that they may respond to long-acting preparations of somatostatin analogs, including octreotide (Sandostatin LAR Depot). For patients who are symptomatic from tumor bulk or carcinoid syndrome, a long-acting somatostatin analog that inhibits hormone secretion from the tumor is the cornerstone of therapy. Subcutaneous injections of octreotide LAR 20–30 mg are required every 4 weeks. In 90% of patients, this results in dramatic relief of carcinoid syndrome symptoms and may control tumor growth for a median of 1 year. Options at disease progression include octreotide dose escalation or the addition of everolimus. For patients with somatostatin receptor–positive disease on imaging, another option after progression is treatment with PRRT, which consists of a somatostatin analog conjugated to a radioactive isotope such as yttrium-90 or lutetium-177. Studies of antiangiogenic kinase inhibitors, such as sunitinib and regorafenib, have shown some benefit. In select patients with hepatic-dominant disease, resection of hepatic metastases or tumor debulking by liver-directed chemoembolization or radioembolization may provide dramatic improvement of carcinoid syndrome symptoms.

Patients with advanced, poorly differentiated intestinal NECs are treated in a similar fashion to those with small cell carcinomas. They have a poor prognosis.

Prognosis

The prognosis for patients with GEP-NETs is variable, depending on the tumor grade and stage. Patients with well- or moderately well-differentiated GEP-NETs have a better survival than those with poorly differentiated tumors. Smaller tumors without detectable metastases have a much lower chance of recurrence after surgery. However, most patients with GEP-NETs are stage IV with hepatic metastases by the time of diagnosis. Nevertheless, low-grade metastases may be indolent or slow-growing and may respond to octreotide or lanreotide.

The surgical complication rate for GEP-NETs is about 40%. Extensive pancreatic resection may cause diabetes mellitus. EUS-RFA is effective for most patients with pNETs up to 3 cm, even those with multiple tumors. For patients with gastrinomas, the 5-, 10-, and 20-year survival rates with MEN 1 are 94%, 75%, and 58%, respectively, while the survival rates for patients with sporadic gastrinomas are 62%, 50%, and 31%, respectively.

CANCERS OF THE GENITOURINARY TRACT

PROSTATE CANCER

ESSENTIALS OF DIAGNOSIS

- Prostatic induration on DRE or elevation of PSA.
- Most often asymptomatic.
- Rarely: systemic symptoms (weight loss, bone pain).

General Considerations

Prostate cancer is the most common noncutaneous cancer and the second leading cause of cancer-related death in American men with an estimated 299,010 new prostate cancer diagnoses and 35,250 prostate cancer deaths in 2024. *The clinical incidence, however, does not match the prevalence of the disease.* Autopsy studies have demonstrated that > 40% of men over age 50 years have prostate cancer, and its prevalence increases with age with 30% of men aged 60–69 years and 67% of men aged 80–89 years harboring the disease at autopsy. Prostate cancer is an extremely heterogenous disease and most of these occult cancers are small, indolent, and organ-confined with little potential for regional or metastatic disease. Although the global prevalence of prostatic cancer at autopsy is relatively consistent, the clinical incidence varies considerably (highest in North America, Europe, the Caribbean, Australia/New Zealand, and Southern Africa, and lowest in Northern Africa and Asia). *Globally, prostate cancer is the second most common malignancy in men and the fifth leading cause of cancer mortality.*

Clinical Findings

A. Symptoms and Signs

Most prostate cancers are asymptomatic and are diagnosed because of elevations in serum PSA. However, some cases of prostate cancer are diagnosed based on discrete nodules or areas of induration within the prostate on a DRE. Obstructive voiding symptoms are most often due to benign prostatic hyperplasia, which occurs in the same age group. Nevertheless, large or locally extensive prostatic cancers can cause obstructive voiding symptoms, including urinary retention. Lymph node metastases can lead to lower extremity lymphedema, though this is extremely unusual. Because the axial skeleton is the most common site of metastases, patients may present with back pain, pathologic fractures, or rarely neurologic symptoms from epidural metastases and cord compression.

B. Laboratory Findings

1. PSA serum tumor marker—PSA is a glycoprotein produced only by prostatic cells, either benign or malignant. The serum level is typically low in men without prostate cancer and correlates with the total volume of prostate tissue and tends to increase with age. Measurement of serum PSA is useful in detecting and staging prostate cancer, monitoring response to treatment, and identifying recurrence before it becomes clinically evident. PSA is not specific for cancer, and there is considerable overlap of values with men with BPH. It is important to realize that a PSA reference range of ≤ 4.0 ng/mL is not appropriate for all men and that *no PSA threshold excludes the diagnosis of prostate cancer* (Table 44–13). More recent data suggest that a man's baseline PSA in his 50s is associated with long-term prostate cancer risk. Median PSA levels for men aged 40–49 years and 50–59 years are 0.7 ng/mL and 0.9 ng/mL, respectively. Baseline PSA level may assist with patient counseling regarding long-term prostate cancer risk and set appropriate screening intervals. Prostate cancer will be diagnosed in approximately 18–30% of men with PSA 4.1–10 ng/mL (4.1–10 mcg/L) and 50–70% of men with PSA > 10 ng/mL (10 mcg/L).

Table 44–13. Risk of prostate cancer in men with PSA ≤ 4.0 ng/mL (or mcg/L).

PSA Level (ng/mL [or mcg/L])	Percentage with Prostate Cancer	Percentage with High-Grade[1] Prostate Cancer
≤ 0.5	6.6	12.5
0.6–1.0	10.1	10.0
1.1–2.0	17.0	11.8
2.1–3.0	23.9	19.1
3.1–4.0	26.9	25.0

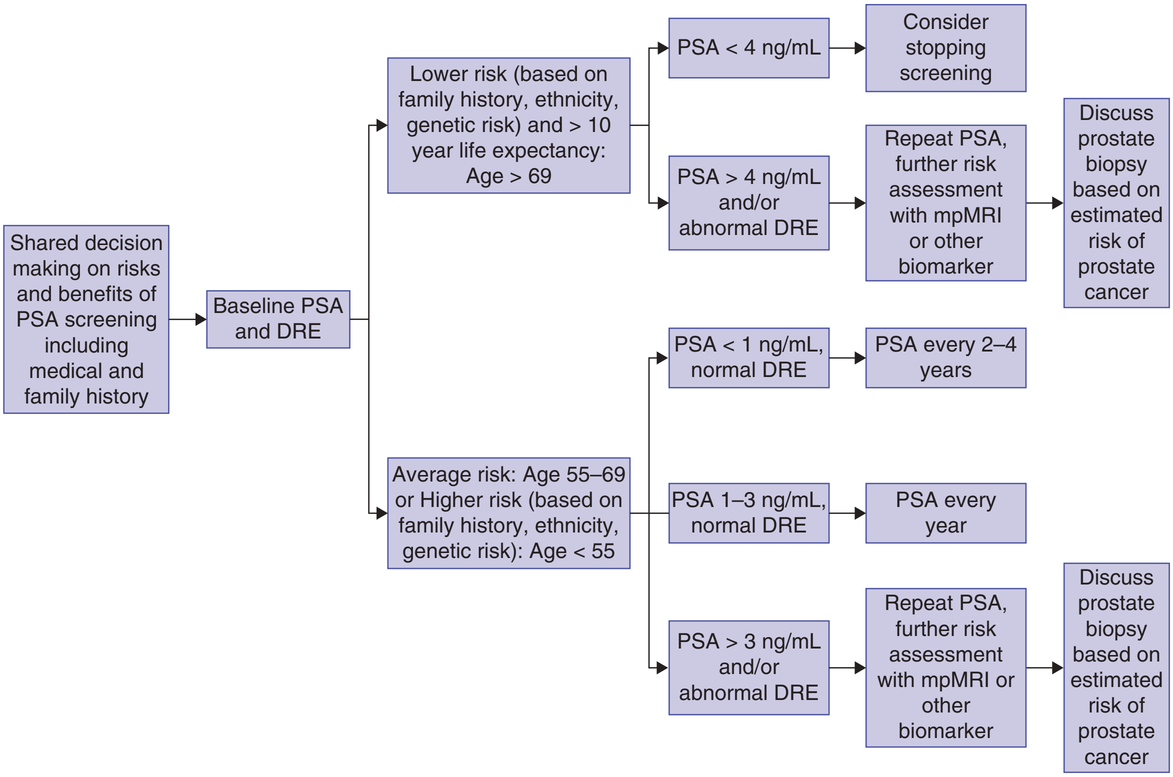
[1] High-grade cancer was defined as Gleason score ≥ 7.

Data from Thompson IM et al. Prevalence of prostate cancer among men with a PSA level ≤ 4.0 ng per milliliter. N Engl J Med. 2004;350:2239.

In untreated patients with prostate cancer, the level of PSA correlates with the volume and stage of disease. Patients with PSA levels < 10 ng/mL (10 mcg/L) usually have localized and therefore potentially curable cancers with local therapy alone, while those with PSA levels > 40 ng/mL (40 mcg/L) are more likely to have advanced disease (seminal vesicle invasion, lymph node involvement, or occult distant metastases). Approximately 98% of patients with metastatic prostate cancer will have an elevated PSA level, yet treatment decisions cannot be made based on PSA testing alone. A rising PSA after therapy is usually consistent with progressive disease, either locally recurrent or metastatic, but does not always indicate that immediate additional therapy is necessary.

2. Miscellaneous laboratory testing—Patients with urinary retention or with ureteral obstruction due to locoregionally advanced prostate cancers may present with elevations in BUN or serum creatinine. Patients with bony metastases may have elevations in serum alkaline phosphatase or calcium. Laboratory and clinical evidence of disseminated intravascular coagulation can occur in patients with advanced prostate cancers.

3. Prostate biopsy—*Ultrasound-guided biopsy is the standard method for detection of prostate cancer.* A decision to recommend a prostate biopsy is generally not made on PSA levels alone but after careful prostate cancer risk assessment by utilizing either a multivariable clinical risk calculator or additional biomarker or imaging studies (Figure 44–2). The use of a spring-loaded, 18-gauge biopsy needle has allowed prostate biopsy to be performed with minimal patient discomfort and morbidity. Local anesthesia is standard and increases the tolerability of the procedure. While a transrectal approach is still most commonly practiced in the United States, rising rates of postbiopsy infection and sepsis have led to increasing utilization of a transperineal approach. This approach has very little risk for infection and often does not require prophylactic antibiotics. Prostate biopsy specimens are taken from all areas



Shared decision making on risks and benefits of PSA screening including medical and family history
Baseline PSA and DRE
Lower risk (based on family history, ethnicity, genetic risk) and > 10 year life expectancy: Age > 69
PSA < 4 ng/mL
Consider stopping screening
PSA > 4 ng/mL and/or abnormal DRE
Repeat PSA, further risk assessment with mpMRI or other biomarker
Discuss prostate biopsy based on estimated risk of prostate cancer
Average risk: Age 55–69 or Higher risk (based on family history, ethnicity, genetic risk): Age < 55
PSA < 1 ng/mL, normal DRE
PSA every 2–4 years
PSA 1–3 ng/mL, normal DRE
PSA every year
PSA > 3 ng/mL and/or abnormal DRE
Repeat PSA, further risk assessment with mpMRI or other biomarker
Discuss prostate biopsy based on estimated risk of prostate cancer

▲ **Figure 44–2.** An algorithm for prostate cancer early detection. DRE, digital rectal examination; mpMRI, multiparametric magnetic resonance imaging.

of the prostate including the apex, mid-portion, base, and anterior gland. While extended-pattern biopsies, including a total of at least 10 biopsies, are associated with improved cancer detection and risk stratification of patients with newly diagnosed disease, suspicious hypoechoic prostatic lesions seen on transrectal ultrasound or pre-biopsy MRI may be targeted for biopsy. Patients with abnormalities of the seminal vesicles can have these structures specifically biopsied to identify local tumor invasion.

C. Imaging

Multiparametric MRI (mpMRI) has emerged as the imaging study of choice for localized prostate cancer detection and characterization. Prior to prostate cancer diagnosis, particularly among men with previous negative prostate biopsies, mpMRI is used to evaluate for suspicious prostatic lesions and to aid in the decision to undergo prostate biopsy. Such lesions may then be sampled via MRI-guided needle biopsy or via MR fusion (in which prostate MRI images are fused in real-time with images from an ultrasound-guided needle biopsy). It has clearly been shown that the use of mpMRI to guide the decision to undergo a prostate biopsy for a rising PSA can reduce unnecessary biopsies and limit detection of indolent disease. High-quality prostate MRI, however, is not universally available and there is considerable interobserver variability with interpretation.

Use of imaging for staging should be tailored to the likelihood of advanced disease in newly diagnosed cases. Asymptomatic patients with low- to intermediate-grade cancers, thought to be localized to the prostate on DRE and transrectal ultrasonography and associated with modest elevations of PSA (ie, < 10 ng/mL [10 mcg/L]), need no further imaging. Cross-sectional imaging with *CT or MRI of the abdomen and pelvis* and *radionuclide (99-technetium) bone scans* are traditionally the first-line staging studies performed, when indicated, to assess for metastases.

Prostate cancer bony metastases tend to be multiple and most commonly occur in the axial skeleton. ^{18}*F-Fluciclovine (Axumin)* and *prostate-specific membrane antigen (PSMA) PET imaging* are approved and now available for initial staging of prostate cancer as well as to evaluate suspected cancer recurrence based on elevated PSA after prior treatment. The FDA has approved ^{68}*Ga PSMA-11, piflufolastat F 18 (Pylarify), and flotufolastat F 18 (Posluma)* injections as PET imaging agents for prostate cancer, which have largely replaced standard nuclear medicine bone scans where available.

D. Genetic and Molecular Testing

The role of genetics and molecular testing in prostate cancer diagnosis and management is evolving. The American Society of Clinical Oncology (ASCO) published guidelines on the use of multigene panels for germline testing in men with prostate cancer. A family history of prostate cancer and certain other malignancies such as breast or ovarian cancer increases the risk of prostate cancer. Additionally, prostate cancer has been associated with several hereditary cancer syndromes (eg, Lynch syndrome, hereditary breast and ovarian cancer syndrome, etc.) with approximately 11% of patients with prostate cancer with at least one additional primary cancer carrying germline pathogenic variations. Consequently, some patients with prostate cancer and their families may have elevated risk for other cancers. Genetic variations, such as in *BRCA1/2*, are associated with lower PSA at diagnosis and increased risk of progression and death; approximately 12% of patients with metastatic prostate cancer have germline pathogenic variations in homologous DNA repair genes. Germline pathogenic genetic variations in DNA repair genes can have implications for treatment and, as a result, play a role in personalized treatment. Patients with prostate cancer should have a thorough review of their family history and those with any concern, referred for genetic counseling and possible testing. Additionally, patients with high-risk disease or metastatic disease should undergo genetic evaluation as well. NCCN guidelines recommend considering germline genetic testing in men presenting with localized high-risk, regionally advanced, or metastatic disease. Commercially available *cancer tissue RNA-based assays* are available for further risk assessment after prostate cancer diagnosis; these may help determine the need for and timing of prostate cancer treatment as well as treatment intensity.

Screening for Prostate Cancer

The impact of prostate cancer screening on mortality remains controversial. PSA-based screening can reduce the risk of prostate cancer–specific mortality, however, when performed in an organized fashion. Two large, randomized trials have evaluated the benefit of PSA screening for early detection of prostate cancer. In the US Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, no mortality benefit was observed after combined screening with PSA testing and DRE during 15-year follow-up. Although screening resulted in a 12% increase in prostate cancer detection, the cancer-specific mortality rate was similar in the screening and control arms (2.55 and 2.44 deaths per 10,000 person-years, respectively). However, an estimated 86% of control patients received at least one screening PSA test and 46% of control patients received yearly PSA screening (versus 99% and 84%, respectively, for the intervention arm) during the trial. This high degree of contamination in the control arm likely impacted the ability of this trial to detect meaningful differences in cancer detection.

Conversely, the European Randomized Study of Screening for Prostate Cancer trial demonstrated a significant 20% reduction in prostate cancer mortality with an absolute reduction of 1.75 deaths per 1000 men screened at 16 years. The number of men needed to be invited for screening to prevent one prostate cancer death was 570 at 16 years compared with 742 at 13 years, while the number of prostate cancers needing to be diagnosed to prevent one prostate cancer death was reduced from 26 to 18, underscoring the importance of adequate long-term follow-up for prostate cancer.

Multiple practice guidelines recommend *discussion and shared decision-making* regarding the risks and benefits of PSA screening and prostate cancer early detection. While PSA measurement is the most widely performed method of screening, DRE is still recommended (Figure 44–2). PSA testing increases the detection rate of prostate cancers compared with DRE alone. Approximately 2–2.5% of men older than 50 years of age will be found to have prostate cancer using PSA testing compared with a rate of approximately 1.5% using DRE alone. PSA is not specific for cancer, and there is considerable overlap of values with men with BPH. PSA-detected cancers are more likely to be localized compared with those detected by DRE alone.

The frequency of PSA testing also remains a matter of debate. The traditional yearly screening approach may not be the most efficient; rather, earlier PSA testing at younger age may allow less frequent testing later and provide information regarding *PSA velocity* (changes in PSA over time). Men with PSA above the age-based median when tested between ages 40–60 years are at significantly increased risk for subsequent cancer detection over 25 years. Men aged 40–50 with PSA below 0.6 ng/mL (0.6 mcg/L) and those aged 50–60 years with PSA below 0.71 ng/mL (0.71 mcg/L) may require less frequent PSA testing. In addition, men with PSA velocity > 0.35 ng/mL (0.35 mcg/L) per year measured 10–15 years before diagnosis had significantly worse cancer-specific survival compared with those with lower PSA velocity. A secondary data analysis from the PLCO trial also demonstrated that baseline PSA for younger men in their 50s can predict long-term risk of prostate cancer and can be used to tailor PSA screening intervals. Men with a baseline PSA of < 1 ng/mL had a 1.5% incidence of prostate cancer at 13 years compared with 29.5% of men with baseline PSA levels > 4 ng/mL. The NCCN guidelines (https://www.nccn.org/professionals/physician_gls/pdf/prostate.pdf) for prostate cancer early detection incorporate many of these factors.

In 2018, the USPSTF issued a revised (Grade C) recommendation for men aged 55–69 years that the decision to undergo periodic PSA-based screening should be an individual one. Before deciding about screening, men should discuss its potential benefits and harms with their clinician, incorporating their own values and preferences in the decision. The revised recommendation acknowledges that, while screening offers some men a small potential benefit of reducing the chance of dying from prostate cancer, many other men will experience potential harms from screening. These include false-positive results that require additional testing and possible prostate biopsy; overdiagnosis and overtreatment of non–life-threatening disease; and treatment complications, such as incontinence and erectile dysfunction. In determining whether screening is appropriate in individual cases, the individual patient's family history, race/ethnicity, comorbid medical conditions, values about the benefits and harms of screening and treatment-specific outcomes, and other health needs should be considered. Clinicians should not screen men who do not express a preference for screening. For men aged 70 years or older, the USPSTF recommends against PSA-based screening (Grade D recommendation). The 2023 AUA/SUO guidelines on early detection of prostate cancer advise clinicians to engage in shared decision-making with men in whom prostate cancer screening would be appropriate, incorporating the patient's values and preferences. This update provides important information for clinicians on deciding when to start screening men and how often. (See https://www.auanet.org/guidelines-and-quality/guidelines/early-detection-of-prostate-cancer-guidelines.)

In general, *PSA levels in isolation should not be used to guide decisions regarding the need for prostate biopsies.* Additional biomarkers and imaging are now widely used to improve risk stratification for early detection of life-threatening prostate cancers. These also include establishment of age- and race-specific reference ranges, measurement of free serum and protein-bound levels of PSA (*percent free PSA*), and calculation of PSA velocity. Generally, men with PSA free fractions exceeding 25% are unlikely to have prostate cancer, whereas those with free fractions < 10% have an approximately 50% chance of having prostate cancer. Additional commercially available serum- and urine-based tests, including the Select MDx, Prostate Health Index and 4kscore, and ExoDx, may better identify not only men at greater risk for prostate cancer but those with more aggressive disease. mpMRI is also frequently used in the screening setting after a concerning PSA level is found. Multiple studies suggest that incorporating mpMRI into a prostate cancer screening and early detection pathway can lead to fewer negative prostate biopsies while improving overall detection of higher-grade prostate cancers. However, not all prostate cancers are visualized on mpMRI with a negative predictive value of 0.75. There is also variability in MRI quality and interpretation that must be considered when using MRI as a screening test prior to referral to a urologist.

Staging

Most prostate cancers are adenocarcinomas. Most arise in the peripheral zone of the prostate, though a small percentage arise in the central (5–10%) and transition zones (20%) of the gland. Pathologists utilize the *Gleason grading system* whereby a "primary" grade is applied to the architectural pattern of malignant glands occupying the largest area of the specimen and a "secondary" grade is assigned to the next largest area of cancer. Grading is based on architectural rather than histologic criteria, and five "grades" are possible. Adding the score of the primary and secondary grades gives a Gleason score from 2 to 10. In current practice, however, Gleason scores of 2–5 are no longer assigned. Gleason score correlates with tumor volume, pathologic stage, and prognosis. A simplified five-grade group system has been introduced by the International Society of Urological Pathologists; it is based on Gleason score and is now widely utilized on pathology reports.

Treatment

A. General Measures

The optimal management of localized prostate cancer remains controversial owing to the plethora of treatment options, side effects of the various options, and indolent nature of many prostate cancers. These factors have contributed to uncertainty regarding a definitive survival benefit of treating localized prostate cancer. To help guide treatment decision-making, patients are risk stratified according to their PSA level at diagnosis, DRE, prostate cancer grade (Gleason score) and other clinical and pathological features. Multivariable instruments are available online for patients and clinicians to facilitate treatment decisions. Additionally, patients should have an assessment of life expectancy prior to treatment decision-making since all patients with low-risk disease and many with intermediate-risk disease with < 10-year life expectancy will not benefit from immediate treatment. Prognostic tissue-based risk biomarkers are also now available to help guide treatment decisions.

B. Active Surveillance

***Active surveillance** is now the preferred initial treatment recommendation for men with well-differentiated prostate cancer and low-risk clinical features.* The goal of active surveillance is to avoid treatment in men who may never require it while recognizing and definitively treating men harboring higher-risk disease in order to balance cancer risk with the morbidity of treatment. Active surveillance alone may be effective management for appropriately selected patients, typically those with low PSA, small volume, well-differentiated cancers, and life expectancy < 10–15 years. For such patients, active surveillance may involve serial PSA levels, DREs, periodic prostate mpMRI, and biopsies to reassess grade and extent of cancer. *Different than watchful waiting, the goal of active surveillance is to identify early changes in the cancer when curative intervention can still be applied.* Endpoints for intervention in patients on active surveillance, particularly PSA changes, have not been clearly defined and surveillance regimens remain an active area of research. Most men are offered definitive treatment when cancer grade changes are noted on surveillance biopsy. Contemporary series demonstrate freedom from definitive treatment in greater than half of patients at 5 years, and risk of developing metastases and suffering cancer-specific death in < 3% and 2%, respectively, at 10 years. Delayed therapy for clinical signs of progression seems to have no negative impact on survival. Active surveillance is featured prominently in the AUA, NCCN, and EAU guidelines and is the preferred management in most men with low- and some intermediate-risk prostate cancer. This approach is increasingly accepted and incorporated in routine clinical practice.

***Watchful waiting** is the preferred treatment for men with limited life expectancy who can be followed with PSA alone in the absence of any symptoms or signs of metastatic disease.*

C. Radical Prostatectomy

During radical prostatectomy, the seminal vesicles, prostate, and ampullae of the vas deferens are removed. *Refinements in technique have allowed preservation of urinary continence in most patients and erectile function in selected patients.* Radical prostatectomy can be performed via open retropubic or laparoscopic (with or without robotic assistance) surgery. Organ-confined and lower-grade cancers rarely recur; however, cancers with adverse pathologic features (capsular penetration, seminal vesicle invasion) are associated with higher local (10–25%) and distant (20–50%) relapse rates.

Ideal candidates for radical prostatectomy include healthy patients with stages T1 and T2 prostate cancers. Patients with advanced local tumors (T4) or lymph node metastases are rarely candidates for prostatectomy alone, although surgery is sometimes used in combination with hormonal therapy and postoperative radiation therapy for select high-risk patients. Twenty-nine-year follow-up from the Scandinavian Prostate Cancer Group Study Number 4 randomized trial comparing radical prostatectomy to watchful waiting in men with localized prostate cancer demonstrated a prostate cancer survival advantage with surgery with an absolute difference in risk of 11.7%. The ProtecT trial randomized 1632 primarily low- and intermediate-risk men with clinically localized prostate cancer to either active monitoring, surgery, or radiotherapy. At 15 years follow-up, prostate cancer–specific mortality was low in all three groups and differences were not significant, though both surgery and radiotherapy were associated with lower rates of disease progression and metastases. An undetectable PSA (< 0.1 ng/mL) after surgery suggests no signs of residual or recurrent disease and no further imaging or treatment is required.

D. Radiation Therapy

Radiation can be delivered by a variety of techniques to the prostate and, when clinically indicated, to the pelvic lymph nodes. Conformal techniques, including three-dimensional conformal radiation, intensity-modulated radiotherapy, and image-guided radiotherapy, have become the standard of care for *external photon-based radiotherapy,* while *proton beam therapy* has gained acceptance as an alternative external beam therapy that theoretically may reduce toxicities. Additionally, hypofractionated and ultra-hypofractionated (ie, *stereotactic radiotherapy*) regimens have shown promising short- and intermediate-term outcomes versus conventionally dosed regimens. Low- and high-dose rate *brachytherapy*—the implantation of permanent or temporary radioactive sources (palladium, iodine, or iridium) into the prostate—can be used as monotherapy in those with low-grade or low-volume malignancies or combined with external beam radiation in patients with higher-grade or higher-volume disease. The PSA may initially rise after brachytherapy because of prostate inflammation and necrosis. This transient elevation (“PSA bounce”) should not be mistaken for recurrence and may occur up to 20 months after treatment. Patients with intermediate- and high-risk disease benefit from concomitant *androgen deprivation therapy (ADT)* for a specified period, which can be up to several years for men with high-grade, high-volume disease. As with surgery, the likelihood of local failure following radiation correlates with technique and cancer characteristics. The likelihood of a positive prostate biopsy > 18 months after radiation varies between 20% and 60%. Patients with local recurrence are at an increased risk of cancer progression and cancer death compared with those who have negative biopsies. Survival of patients with localized cancers (T1, T2, and selected T3) approaches 65% at 10 years. Ambiguous target definitions, inadequate radiation doses, and understaging of the cancer may be responsible for the failure noted in some series.

E. Focal Therapy

To reduce the morbidity of localized prostate cancer treatment, there has been a growing interest in focal therapy. Focal therapy delivers energy to the prostate, destroying the tumor(s) and a margin of normal prostate tissue while avoiding collateral damage to the neurovascular bundles, external urinary sphincter, bladder, and rectum. To date, several energy sources such as cryotherapy, high-intensity focused ultrasound, lasers, and irreversible electroporation have been evaluated and are in clinical use. Clinical practice guidelines recognize that the role for ablative therapies is largely unknown, but they can be offered to well-informed men with intermediate-risk disease, preferably in the setting of a clinical trial or registry.

F. Treatment for Locally and Regionally Advanced Disease

Those patients with high-risk or locally extensive cancers, including seminal vesicle and bladder neck invasion, are at increased risk for both local and distant relapse despite local therapy and often require multimodal approaches to treatment. Patients with advanced pathologic stage or positive surgical margins after prostatectomy are at an increased risk for local and distant tumor relapse. Due to these risks, such patients have been considered for *adjuvant therapy* (radiation for positive margins and seminal vesicle invasion, or androgen deprivation or radiation, or both, for lymph node metastases). Two RCTs demonstrated improved progression-free and metastasis-free survival with early radiotherapy in these men, and subsequent analysis showed improved overall survival in men receiving adjuvant radiation therapy. However, the publication of multiple trials comparing adjuvant radiotherapy with early-salvage therapy for detectable or rising PSA using contemporary radiotherapy techniques demonstrated no difference in 5-year biochemical progression-free survival, casting doubt on the benefit of adjuvant radiotherapy. Guidelines recommend PSA monitoring after treatment with early salvage therapy for recurrence. The EMBARK clinical trial demonstrated improved metastases free survival with enzalutamide with or without ADT over ADT alone for men with PSA recurrent, non-metastatic prostate cancer after primary therapy (radiation or prostatectomy) and rapid PSA doubling time of < 9 months.

G. Metastatic Disease

Since death due to prostate carcinoma is almost invariably the result of failure to control metastatic disease, research has emphasized efforts to improve control of distant disease. Most prostate carcinomas are hormone dependent, and 70–80% of men with metastatic prostate carcinoma will respond to various forms of androgen deprivation. *Androgen deprivation therapy* may be effective at several levels along the pituitary–gonadal axis using a variety of methods or agents (Table 44–14). Use of LH-releasing hormone (LHRH) agonists (leuprolide, goserelin) achieves medical castration without orchiectomy and is the most common method of reducing testosterone levels. Both degarelix and relugolix are FDA-approved LHRH

Table 44–14. Androgen deprivation for prostate cancer (listed in alphabetical order, by level).

Level	Agent	Dose	Sequelae
Adrenal	Ketoconazole	400 mg three times orally daily	Adrenal insufficiency, nausea, rash, ataxia
	Corticosteroid Prednisone	20–40 mg orally daily	GI bleeding, fluid retention
	CYP17a1 inhibitor Abiraterone	1000 mg orally daily (with prednisone 5 mg orally twice daily)	Weight gain, fluid retention, hypokalemia, hypertension
Pituitary, hypothalamus	**LHRH agonists** Leuprolide Goserelin Triptorelin Histrelin	Daily subcutaneous injection Monthly to quarterly depot injection Monthly depot injection Annual subcutaneous implant	Erectile dysfunction, hot flushes, gynecomastia, rarely anemia
	LHRH antagonist Degarelix	240 mg subcutaneously initial dose, then 80 mg subcutaneously monthly	Hot flushes, weight gain, erectile dysfunction, increased liver tests
Prostate	**Antiandrogens** Flutamide	250 mg three times orally daily	No erectile dysfunction when used alone; nausea, diarrhea
	Bicalutamide	50 mg orally daily	Liver, cardiac, and pulmonary toxicity
	Enzalutamide	160 mg orally daily	Seizures, dizziness, asthenia
	Apalutamide	240 mg orally daily	Fatigue, leukopenia, hyperlipidemia, hyperglycemia, hyperkalemia, seizures (rare)
	Darolutamide	600 mg orally twice daily	Fatigue, extremity pain, rash
	Cytotoxic chemotherapeutic agents Docetaxel	75 mg/m^2 intravenously once on day 1 of 21-day cycle (with prednisone 10 mg orally daily)	Bone marrow, skin, pulmonary, cardiac, GI, hepatic toxicities possible
	Cabazitaxel	20 mg/m^2 intravenously once on day 1 of 21-day cycle (with prednisone 10 mg orally daily)	
Testis	Orchiectomy		Gynecomastia, hot flushes, erectile dysfunction

LHRH, LH-releasing hormone.

antagonists and have no short-term testosterone "flare" associated with LHRH agonists. Because of its rapid onset of action, *ketoconazole* should be considered in patients with advanced prostate cancer who present with spinal cord compression, bilateral ureteral obstruction, or disseminated intravascular coagulation. Although testosterone is the major circulating androgen, the adrenal gland secretes the androgens dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione. In addition to immediate side effects of androgen deprivation (sexual dysfunction and hot flashes), the chronic suppression of testosterone leads to osteoporosis and risk of fractures, CVD and diabetes mellitus, and decreased muscle and increased fat. *Bisphosphonates* can prevent osteoporosis associated with androgen deprivation, decrease bone pain from metastases, and reduce skeletal-related events. *Denosumab*, a RANK ligand inhibitor, is approved for the prevention of skeletal-related events in patients with bone metastases from prostate cancer and also appears to delay the development of these metastases in patients with castration-resistant prostate cancer.

The management of advanced prostate cancer is rapidly evolving and is now initially based on the volume of metastatic disease at the time of diagnosis. Contemporary management consists of more than androgen deprivation therapy with orchiectomy, LHRH agonist, or LHRH antagonist alone and may even include radiation therapy to the primary tumor. Patients at risk for disease-related symptoms (bone pain, obstructive voiding symptoms) should receive *concurrent antiandrogens* due to the initial elevation of serum testosterone that accompanies LHRH agonists. For patients with hormone-naïve metastatic prostate cancer, the addition of systemic cytotoxic chemotherapy with *docetaxel* to androgen deprivation therapy results in improved survival compared with androgen deprivation therapy alone in men with high-volume disease. Similarly, the addition of *abiraterone acetate plus prednisone* to androgen deprivation therapy results in superior survival compared with androgen deprivation therapy alone. Results from the PEACE-1 trial demonstrate that a three-drug regimen, with androgen deprivation therapy, docetaxel, and abiraterone acetate used together for men with high-volume metastatic prostate cancer, provides the best survival outcome for men with hormone-naïve metastatic cancer. Other androgen receptor signaling inhibitors such as enzalutamide, apalutamide, or darolutamide are also used in this situation. With this *treatment intensification,* the median survival for men with de novo metastatic prostate cancer is now expected to be 5 years. A benefit of local external beam radiation therapy to the prostate gland was demonstrated by STAMPEDE in which patients with low-volume metastatic disease who received external radiotherapy plus standard systemic therapy had improved overall survival compared with those who received only standard systemic therapy. Although under investigation, radical prostatectomy is not performed in patients with metastatic disease.

Patients with *castrate-resistant disease* or prostate cancer that demonstrates rising PSA or progression of disease despite castrate levels of serum testosterone (< 50 ng/dL) should continue their LHRH agonist/antagonist regimen. Additional treatment options are stratified based on the presence of metastatic disease. Patients with nonmetastatic castrate-resistant disease and long PSA doubling time (longer than 10 months) can simply be observed due to their relatively indolent disease. Conversely, nonmetastatic castrate-resistant patients with short doubling times (10 months or less) have demonstrated improved metastasis-free survival with the addition of one of the potent nonsteroidal androgen receptor antagonists, enzalutamide, apalutamide, or darolutamide, to androgen deprivation therapy. For patients with metastatic castrate-resistant prostate cancer, docetaxel was the first cytotoxic chemotherapy agent to improve survival. Enzalutamide and abiraterone improve overall survival in men with metastatic castrate-resistant prostate cancer in both the docetaxel-naïve and non-naïve setting. Cabazitaxel is a second-line taxane chemotherapy that improves overall survival in men who have received docetaxel. Sipuleucel-T, an autologous cellular immunotherapy, is FDA-approved in asymptomatic or minimally symptomatic men with metastatic castration-resistant prostate cancer. Radium-223 dichloride is approved for the treatment of men with castration-resistant, symptomatic bone metastases, with significant improvements in both overall survival and time to skeletal-related events (eg, fractures and spinal cord compression). Lutetium-177-PSMA-617 is the first theranostic radioligand agent for metastatic castration-resistant prostate cancer and is approved for use in men with PSMA-producing tumors who have progressed on other lines of therapy including chemotherapy.

Guidelines recommend genomics testing for all men with metastatic prostate cancer as men who are found to have specific germline or somatic pathogenic variants may benefit from personalized treatment strategies. Poly-ADP-ribose polymerase (PARP) inhibitors represent a class of anticancer agents with some activity against prostate cancer particularly in those patients harboring pathogenic variants in genes important for homologous recombination such as *BRCA1*, *BRCA2*, and *ATM*. Multiple PARP inhibitors are now approved for men with metastatic prostate cancer and may be given in combination with other hormonal agents.

Prognosis

The likelihood of success of active surveillance or treatment can be predicted using risk assessment tools that usually combine stage, grade, PSA level, and number and extent of positive prostate biopsies. Several web-based tools are available (eg, https://www.mskcc.org/nomograms/prostate). Widely used nomograms include the *Kattan* nomogram and the *CAPRA* nomogram. CAPRA uses serum PSA, Gleason score, clinical stage, percent positive biopsies, and patient age in a point system to risk stratify and predict the likelihood of PSA recurrence 3 and 5 years after radical prostatectomy as well as metastasis and prostate cancer–specific and overall survival. The CAPRA nomogram has been validated on large multicenter and international radical prostatectomy and radiation-treated cohorts.

The patterns of prostate cancer progression have been well defined. Small and well-differentiated cancers (Gleason grade 3) are usually confined within the prostate, whereas large-volume (> 4 mL) or poorly differentiated (Gleason grades 4 and 5) cancers are more often locally extensive or metastatic to regional lymph nodes or bone. Penetration of the prostate capsule by cancer is common and occurs along perineural spaces. Seminal vesicle invasion is associated with a high likelihood of regional or distant disease and disease recurrence. The most common sites of lymph node metastases are the obturator and internal iliac lymph node chains and of distant metastases, the axial skeleton.

When to Refer

- Refer all patients to a urologist for management of localized disease or for active surveillance.
- For metastatic disease, medical oncology should be consulted for consideration of systemic treatments.
- Active surveillance may be appropriate in selected patients with very low-volume, low-grade prostate cancer.
- Localized disease may be managed by active surveillance, surgery, or radiation therapy.
- Locally extensive, regionally advanced, and metastatic disease often require multimodal treatment strategies.

BLADDER CANCER

ESSENTIALS OF DIAGNOSIS

- Gross or microscopic hematuria.
- Irritative voiding symptoms.
- Positive urinary cytology in most patients.
- Filling defect within bladder noted on imaging.

General Considerations

Bladder cancer is the second most common urologic cancer; it occurs more commonly in men than women (3.1:1), and the mean age at diagnosis is 73 years. In 2024 in the United States, it is estimated that approximately 83,190 cases of bladder cancer will be diagnosed and 16,840 deaths will result. Cigarette smoking and exposure to industrial dyes or solvents are risk factors for the disease and account for approximately 60% and 15% of new cases, respectively. In the United States, almost all primary bladder cancers (98%) are epithelial malignancies, usually urothelial cell carcinomas (90%). Adenocarcinomas and squamous cell cancers account for approximately 2% and 7%, respectively. The latter is often associated with schistosomiasis, vesical calculi, or prolonged catheter use.

Clinical Findings

A. Symptoms and Signs

Hematuria—gross or microscopic, chronic or intermittent—is the presenting symptom in 85–90% of patients with bladder cancer (see Hematuria in Chapter 26). Irritative voiding symptoms (urinary frequency and urgency) occur in a small percentage of patients as a result of the location or size of the cancer. Most patients with bladder cancer do not have signs of the disease because of its superficial nature. Abdominal masses detected on bimanual examination may be present in patients with large-volume or deeply infiltrating cancers. Hepatomegaly or palpable lymphadenopathy may be present in patients with metastatic disease, and lymphedema of the lower extremities results from locally advanced cancers or metastases to pelvic lymph nodes.

B. Laboratory Findings

UA reveals microscopic or gross hematuria in the majority of cases. On occasion, hematuria is accompanied by pyuria. Azotemia may be present in a small number of cases associated with ureteral obstruction. Anemia may occasionally be due to chronic blood loss or to bone marrow metastases. Exfoliated cells from normal and abnormal urothelium can be readily detected in voided urine specimens. Cytology can be useful to detect the disease initially or to detect its recurrence. Cytology is sensitive in detecting cancers of higher grade and stage (80–90%), but less so in detecting noninvasive or well-differentiated lesions (50%). There are other novel urinary tumor markers under investigation for screening or assessing recurrence, progression, prognosis, or response to therapy.

C. Imaging

Bladder cancers may be identified as masses within the bladder using ultrasound, CT, or MRI. However, the presence of cancer is confirmed by cystoscopy and biopsy, with imaging primarily used to evaluate the upper urinary tract and to stage more advanced lesions.

D. Cystourethroscopy and Biopsy

The diagnosis and staging of bladder cancers are made by cystoscopy and transurethral resection. If cystoscopy—usually performed under local anesthesia—confirms the presence of a bladder tumor, the patient is scheduled for transurethral resection under general or regional anesthesia. Random bladder and transurethral prostate biopsies are occasionally performed to detect occult disease and potentially identify patients at greater risk for cancer recurrence and progression.

Pathology & Staging

Grading is based on cellular features: size, pleomorphism, mitotic rate, and hyperchromatism. Bladder cancer staging is based on the extent (depth) of bladder wall penetration and the presence of regional or distant metastases. Both cancer grade and stage influence the natural history of bladder cancer including local recurrence within the bladder and progression to higher-stage disease. Several bladder cancer variant histologies have been described and are important for both prognosis and treatment planning.

Treatment

Patients with non–muscle-invasive cancers (Tis, Ta, T1) are treated with complete *transurethral resection* with selective use of a *single dose intravesical chemotherapy* immediately following resection. Patients with carcinoma in situ (Tis) and those with high-grade, non–muscle-invasive lesions (Ta or T1) are good candidates for additional intravesical therapy after resection due to a high risk for cancer recurrence and progression with surveillance alone. Patients with high-risk noninvasive cancers are often also treated with re-resection to confirm stage and grade prior to adjuvant intravesical therapy. Some patients with high-grade T1 (particularly recurrent) bladder cancers are recommended for radical cystectomy.

Patients with muscle-invasive (T2+) but still localized cancers are at risk for both nodal metastases and progression and require more aggressive treatment. The gold standard treatment is *neoadjuvant chemotherapy* followed by *radical cystectomy*, which confers a survival advantage versus cystectomy alone. This is particularly important for higher-stage or bulky tumors to improve their surgical resectability. Trimodal bladder preservation therapy consisting of complete transurethral resection, sensitizing systemic chemotherapy, and external beam radiotherapy can offer similar outcomes in optimally selected patients.

A. Intravesical Therapy

Immunotherapeutic or chemotherapeutic agents delivered directly into the bladder via a urethral catheter can reduce the likelihood of recurrence in those who have undergone complete transurethral resection. Most agents are administered weekly for 6–12 weeks. Efficacy may be increased by prolonging contact time to 2 hours. The use of maintenance therapy after the initial induction regimen is beneficial. Common agents include gemcitabine, mitomycin, docetaxel, valrubicin, and bacillus Calmette–Guérin (BCG), with the last being the only agent effective in reducing disease progression. *Induction intravesical BCG is the standard of care for patients with high-risk, non–muscle-invasive bladder cancer or carcinoma in situ after resection.* Nadofaragene firadenovec-vncg was FDA-approved this year for patients with high-risk BCG unresponsive non-muscle-invasive bladder cancer. This is the first approved gene therapy for bladder cancer. Side effects of intravesical chemotherapy include irritative voiding symptoms and hemorrhagic cystitis. Patients in whom symptoms of infection develop from BCG may require antituberculosis therapy. Global BCG supply shortages have limited access to many patients with bladder cancer and novel agents are being tested in ongoing clinical trials.

B. Surgical Treatment

Although transurethral resection is the initial form of treatment for all bladder cancers (since it is diagnostic, it allows for proper staging, and it controls superficial cancers), muscle-invasive cancers require more aggressive treatment. *Partial cystectomy* can be considered in selected patients with solitary lesions at the bladder dome or those with cancer in a bladder diverticulum. *Radical cystectomy* in men entails removal of the bladder, prostate, seminal vesicles, and surrounding fat and peritoneal attachments and in women removal of the bladder, uterus, cervix, urethra, anterior vaginal vault, and usually the ovaries. In women with anterior cancers, vaginal and reproductive organ-sparing surgery can be considered. Bilateral pelvic lymph node dissection is performed in all patients. Randomized trials have demonstrated similar oncologic outcomes and risks of complications with both open and robot-assisted laparoscopic cystectomy; however, robot-assisted techniques result in significantly less blood loss, lower need for blood transfusion, and slightly shorter convalescence. The most common method for urinary diversion involves creating a *conduit of ileum or colon with a stoma that drains urine into an external appliance*. However, in highly selected patients, *continent forms of diversion* can be performed that avoid the necessity of an external appliance.

C. Radiotherapy

External beam radiotherapy delivered in fractions over a 6- to 8-week period is generally well tolerated, but approximately 10–15% of patients will develop bladder, bowel, or rectal complications. Local recurrence is common after radiotherapy alone (30–70%), and it is therefore combined with radiosensitizing systemic chemotherapy to improve complete response and to decrease recurrence rates. *Bladder-preserving chemoradiation* can be offered to those patients seeking to keep their bladder and is best suited for selected patients with solitary T2 or limited T3 tumors without ureteral obstruction. Radiation with or without chemotherapy can be offered to patients with localized cancers and to patients who are poor candidates for radical cystectomy or to patients with metastatic disease seeking palliation of local symptoms. Salvage cystectomy following primary bladder radiotherapy is more challenging with greater risk of complications.

D. Chemotherapy

Systemic chemotherapy is recommended for eligible patients with muscle-invasive or locally advanced bladder cancer (prior to cystectomy or radiation). The antibody-drug conjugate enfortumab vedotin has replaced chemotherapy as the first-line agent in the metastatic setting (see Other Therapies section). Cisplatin-based combination chemotherapy results in partial or complete responses in 15–45% of patients (Table 44–2) and is the preferred approach. Combination chemotherapy has been used to decrease recurrence rates in patients treated both with surgery and with radiotherapy. Patients who are not eligible for cisplatin should proceed with immediate cystectomy or consider enrollment in a clinical trial. Chemotherapy should also be considered before surgery in those with bulky lesions or those in whom regional metastases are suspected. A multicenter clinical trial showed improved 3-year progression-free survival with dose-dense methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC) neoadjuvant chemotherapy versus a gemcitabine/cisplatin regimen. Alternatively, adjuvant chemotherapy has been used after cystectomy in patients at high risk for recurrence, such as those who have lymph node involvement or extravesical local invasion.

Metastatic disease is present in 15% of patients with newly diagnosed bladder cancer. Furthermore, metastases develop in up to 40% of patients within 2 years of cystectomy, including those patients who were believed to have localized disease at the time of treatment.

E. Immunotherapy

The FDA has approved several checkpoint inhibitors as immunotherapy for patients with urothelial cancer at various stages. Approved anti–PDL-1 inhibitors include atezolizumab, durvalumab, and avelumab (Table 44–2). Approved anti-PD1 inhibitors include nivolumab and pembrolizumab. All are approved for second-line treatment of locally advanced or metastatic urothelial cancer that progressed during or after platinum-based chemotherapy. Nivolumab is FDA-approved for use in combination with cisplatin and gemcitabine for the first-line treatment of adults with unresectable or metastatic urothelial carcinoma. Atezolizumab and pembrolizumab are approved as first-line therapy in cisplatin-ineligible patients whose tumors express PD-L1 or in patients ineligible for any platinum-based chemotherapy regardless of PD-L1 expression status. The KEYNOTE-361 randomized trial failed to show any benefit to adding pembrolizumab to chemotherapy in the first-line setting for patients with metastatic disease. Overall response rates of these agents are similar and range from 17% to 25% in locally advanced and metastatic urothelial bladder cancer. In many cases, responses to therapy are durable. Based on a single arm, phase 2 study, pembrolizumab is now FDA-approved for patients with high-risk, non–muscle-invasive bladder cancers who have failed intravesical BCG therapy. Nivolumab has also been approved in the adjuvant setting after radical cystectomy or nephroureterectomy for patients with urothelial carcinoma who are considered at high risk for recurrence. The phase 3 Niagara trial demonstrated improved event-free and overall survival with neoadjuvant chemotherapy and perioperative durvalumab compared to chemotherapy alone for patients with muscle-invasive bladder cancer undergoing cystectomy.

F. Other Therapies

Enfortumab vedotin is the first antibody-drug conjugate approved for advanced and metastatic urothelial carcinoma. The antibody targets Nectin-4 and demonstrates a 44% response rate (including 12% complete response) in patients who have progressed after multiple other lines of therapy. The EV302 trial showed dramatically improved survival rates with combination enfortumab vedotin and pembrolizumab over platinum-based chemotherapy alone and should be considered first-line therapy for metastatic urothelial carcinoma.

Activating pathogenic variants in the FGFR are common in urothelial carcinomas. The FGFR inhibitor erdafitinib is approved after initial therapy for patients with progressive metastatic urothelial carcinoma whose tumors harbor these mutations with expected response rates of up to 40%.

Prognosis

The frequency of recurrence and progression are correlated with grade. Whereas progression may be noted in few low-grade cancers (19–37%), it is common with poorly differentiated lesions (33–67%). Carcinoma in situ is most often found in association with papillary bladder cancers. Its presence identifies patients at increased risk for recurrence and progression.

At initial presentation, approximately 50–80% of bladder cancers are non–muscle-invasive: stage Ta, Tis, or T1. When properly treated, lymph node metastases and progression are uncommon in such patients and survival is excellent (81%). Five-year survival of patients with T2 and T3 disease ranges from 50% to 75% after radical cystectomy. Long-term survival for patients with metastatic disease at presentation is rare.

When to Refer

- Refer all patients to a urologist. Hematuria usually deserves evaluation with both upper urinary tract imaging and cystoscopy, particularly in a high-risk group (eg, older people).
- Refer when histologic diagnosis and staging require endoscopic resection of cancer.
- Muscle-invasive and locally advanced tumors should be referred to a urologist and medical oncologist since treatment requires multidisciplinary care.
- Metastatic urothelial cancer should be managed by a medical oncologist.

CANCERS OF THE URETER & RENAL PELVIS

Cancers of the ureter and renal pelvis are rare and occur more commonly in patients who have bladder cancer, Balkan nephropathy, or Lynch syndrome, patients who smoke, or those who have a long history of analgesic abuse. The majority are urothelial cell carcinomas. Gross or microscopic hematuria is present in most patients; flank pain secondary to bleeding and obstruction occurs less commonly. As with bladder cancers, urinary cytology is often positive in high-grade cancers. The most common signs identified at the time of CT or intravenous urography include an intraluminal filling defect, unilateral nonvisualization of the collecting system, and hydronephrosis. Ureteral and renal pelvic tumors must be differentiated from calculi, blood clots, papillary necrosis, or inflammatory and infectious lesions. Upper urinary tract lesions are accessible for diagnostic biopsy, fulguration, or resection using a ureteroscope. Treatment is based on the site, size, grade, depth of penetration, and number of cancers present. Endoscopic resection may be indicated in patients with limited renal function or focal, low-grade, cancers. Chemoablation with a mitomycin infused gel can be performed in very select patients with low-grade upper tract lesions. Most high-grade and high-volume cancers are excised with robotic, laparoscopic, or open nephroureterectomy (renal pelvic and upper ureteral lesions) or segmental excision of the ureter (distal ureteral lesions).

A phase 3, randomized trial demonstrated significantly improved 3-year disease-free survival with dual agent adjuvant systemic chemotherapy after nephroureterectomy. Like with urothelial bladder cancers, use of chemotherapy prior to surgery may also improve outcomes and remains under investigation.

Leow JJ et al. Neoadjuvant and adjuvant chemotherapy for upper tract urothelial carcinoma: a 2020 systematic review and meta-analysis, and future perspectives on systemic therapy. Eur Urol. 2021;79:635. [PMID: 32798146]

RENAL CELL CARCINOMA

ESSENTIALS OF DIAGNOSIS

- Gross or microscopic hematuria.
- Flank pain or mass in some patients.
- Systemic symptoms such as fever, weight loss may be prominent.
- Solid renal mass on imaging.

General Considerations

Kidney (renal cell) and renal pelvis carcinomas account for 3.8% of all adult cancers. In 2024 in the United States, it is estimated that approximately 81,610 cases of renal cell carcinoma will be diagnosed and 14,390 deaths will result. Renal cell carcinoma has a peak incidence in the sixth decade of life and a male-to-female ratio of 2:1. It may be associated with several paraneoplastic syndromes.

Risk factors include physical inactivity, obesity, and diabetes mellitus. Cigarette smoking is the only known significant environmental risk factor. Renal cell carcinoma occurs in both sporadic and hereditary forms. There are several hereditary syndromes with autosomal dominant inheritance that can include renal cell carcinoma; these are important to consider when evaluating a patient with suspected kidney cancer (Table 44–15). There is an association with dialysis-related acquired cystic disease and specific genetic aberrations (eg, Xp11.2 translocation). Sporadic renal cell carcinoma is far more common than hereditary forms.

Renal cell carcinoma originates from the proximal tubule cells. Various histologic cell types are recognized (clear cell, papillary, chromophobe, collecting duct, and sarcomatoid). The WHO updated the pathologic classification of RCC types in 2022, which includes a group of molecularly defined subtypes. Histology, immunohistochemistry, molecular signatures, and clinical aspects all vary by renal cell carcinoma type and assist with prognosis prediction and treatment decisions. Hereditary leiomyomatosis and renal cell carcinoma (HLRCC) is the most common hereditary syndrome.

Clinical Findings

A. Symptoms and Signs

Historically, 60% of patients presented with gross or microscopic hematuria. Flank pain or an abdominal mass was detected in approximately 30% of cases. The triad of flank pain, hematuria, and mass, found in only 10% of patients, is often a sign of advanced disease. Fever can occur as a paraneoplastic symptom. Symptoms of metastatic disease (cough, bone pain) occur in 20–30% of patients at presentation. Due to the widespread use of ultrasound and cross-sectional imaging, renal tumors are *frequently detected incidentally* in individuals with no urologic symptoms. Consequently, there has been profound stage migration toward lower stages of disease over the last 20 years with increased detection of small, indolent tumors. Population mortality rates have remained relatively stable.

B. Laboratory Findings

Contemporary studies suggest hematuria is present in < 50% of patients. Erythrocytosis from increased erythropoietin production occurs in 5%, though anemia is more common; hypercalcemia may be present in up to 10% of patients. *Stauffer syndrome* is a reversible syndrome of hepatic dysfunction (with elevated liver tests) in the absence of metastatic disease.

Table 44–15. Hereditary syndromes with autosomal dominant inheritance that can include renal cell carcinoma (listed in alphabetical order).

Syndrome	Gene	Renal Tumor Histology	Associated Clinical Findings
Birt-Hogg-Dubé syndrome (BHD)	*FLCN 17p11.2*	HLRCC-associated RCC	Cutaneous fibrofolliculomas (facial). pulmonary cysts, spontaneous pneumothorax
Hereditary leiomyomatosis and renal cell carcinoma (HLRCC)	*FH 1q42.1*	Papillary	Cutaneous leiomyomas, uterine fibroids
Hereditary papillary renal carcinoma (HPRC)	*MET 7q34*	Chromophobe, oncocytoma, papillary, clear cell	None
von Hippel-Lindau disease (VHL)	*VHL 3p26*	Clear cell	CNS and retinal hemangioblastomas, pheochromocytoma, PNET, cystadenoma of pancreas, broad ligament, epididymis

Modified with permission from Haas NB, Nathanson KL. Hereditary kidney cancer syndromes. Adv Chronic Kidney Dis. 2014;21:81.

C. Imaging

Solid renal masses are often first identified by abdominal ultrasonography or CT. CT and MRI scanning are the most valuable imaging tests for renal cell carcinoma. These scans confirm the character of the mass and provide valuable staging information with respect to regional lymph nodes, renal vein or vena cava tumor thrombus, and adrenal or liver metastases. CT and MRI also provide valuable information regarding the contralateral kidney (function, bilaterality of neoplasm). CXR or CT excludes pulmonary metastases. Bone scans should be performed for large tumors and in patients with bone pain or elevated serum alkaline phosphatase levels. Brain imaging should be obtained in patients with high metastatic burden or in those with neurologic deficits.

Differential Diagnosis

Solid renal masses are renal cell carcinoma until proven otherwise. Other solid masses include renal angiomyolipomas (fat density usually detectable by CT), renal pelvis urothelial cancers (more central location, involvement of the collecting system, positive urinary cytology), renal oncocytomas (indistinguishable from renal cell carcinoma preoperatively with standard imaging), renal abscesses, and adrenal tumors (anterosuperior to the kidney).

Treatment

Surgical extirpation is the primary treatment for localized renal cell carcinoma. Patients with a single kidney, bilateral lesions, or significant medical renal disease should be considered for *partial nephrectomy.* Patients harboring a small cancer with a normal contralateral kidney and good kidney function are also candidates for partial nephrectomy, while *radical nephrectomy* is indicated in patients with cancers larger than 7 cm and those in whom partial nephrectomy is not technically feasible. Radiofrequency and cryosurgical ablation are alternative options instead of surgery in select patients with cancers < 3–4 cm with similar risk of metastatic progression but higher risk of local recurrence. Active surveillance is warranted in select patients (significant comorbidity, short life expectancy) and appears safe with low risk of 5-year systemic progression. Percutaneous biopsy can provide tumor histology and grade to help guide treatment decisions.

Cytotoxic chemotherapy has no role in the treatment of metastatic renal cell carcinoma. Historically, cytokine-based immunotherapies, such as interferon-α and interleukin-2, produced partial response rates of 15–20% and 15–35%, respectively (Table 44–2). Responders tended to have lower tumor burden, metastatic disease confined to the lung, and a high-performance status. Two randomized trials demonstrating a survival benefit of cytoreductive nephrectomy followed by systemic interferon-α compared with the use of systemic therapy alone led to the widespread adoption of cytoreductive nephrectomy. Patients most likely to benefit from cytoreduction were those with good performance status, lung only metastases, and good prognostic features.

The treatment of metastatic renal cell carcinoma has evolved rapidly over the last decade. Presently, management strategies are based on tumor histology (initial treatment choices are based on clear cell versus non–clear cell histology) and patient risk (favorable, intermediate, or poor). Risk is typically assessed according to the *International Metastatic RCC Database Consortium criteria* which includes the number of metastatic lesions at diagnosis. Targeted medications, specifically VEGF, Raf kinase, receptor tyrosine kinases, and mTOR inhibitors, are effective (40–60% response rates) in patients with advanced kidney cancer (Table 44–2). These oral agents, which include sunitinib, pazopanib, cabozantinib, axitinib, sorafenib, and lenvatinib, are generally well tolerated and particularly active for clear cell carcinoma. Sunitinib is approved for adjuvant use after complete surgical resection in patients with adverse pathologic features. The mTOR inhibitors everolimus and temsirolimus are approved for use in patients with prior anti-VEGF therapy, as is the combination of lenvatinib and everolimus. Immunotherapies have also dramatically improved the treatment landscape for patients with advanced kidney cancer. Nivolumab is an approved anti-PD-1 immunotherapy for treating metastatic disease that has progressed despite antiangiogenic therapy. Nivolumab in combination with the anti-CTLA4 immunotherapy ipilimumab (objective response rate 42%, complete response rate 9%) and pembrolizumab (anti-PD-1) in combination with the VEGF inhibitor axitinib (objective response rate 59%, complete response rate 5.8%) and lenvatinib in combination with pembrolizumab (objective response rate 71%, complete response rate 16.1%) have proved superior to sunitinib in previously untreated intermediate- and poor-risk metastatic clear cell renal cell carcinoma. Most recently, cabozantinib in combination with nivolumab and ipilimumab showed improved progression-free survival in patients with intermediate and poor prognostic risk advanced renal cell carcinoma over nivolumab or ipilimumab alone. Combination therapy with two or three agents is considered standard first-line treatment for metastatic RCC (Table 44–2). Pembrolizumab is also approved for adjuvant treatment after surgical resection of renal cell carcinoma in patients at high risk for disease recurrence. For patients with VHL disease and renal cell carcinoma, the novel HIF2α inhibitor, belzutifan, led to dramatic size reductions in both renal and non–renal neoplasms and offers a new treatment option. The LITESPARK-005 trial demonstrated superior progression-free survival with belzutifan over everolimus in non-VHL patients with progressive, previously treated advanced clear-cell RCC. Belzutifan is now FDA approved for patients with VHL or metastatic clear cell RCC following immunotherapy or VEGF tyrosine kinase inhibitor therapy. The utilization of *cytoreductive nephrectomy* in combination with contemporary agents has decreased in response to the results of the CARMENA trial in which patients with intermediate- and poor-risk clear cell renal carcinoma had similar survival following cytoreductive nephrectomy with or without sunitinib and adoption of combination immunotherapy regimens (nivolumab plus ipilimumab, pembrolizumab plus axitinib). Still, there remains a role for cytoreductive surgery in select patients with intermediate-risk disease. The SURTIME randomized trial compared immediate versus deferred cytoreductive nephrectomy in patients with metastatic renal cell carcinoma treated with sunitinib and showed an overall survival advantage with the deferred approach. This may serve to identify patients who respond the best to systemic therapy prior to undergoing removal of the primary tumor.

Prognosis

After radical or partial nephrectomy, tumors confined to the renal capsule (T1–T2) demonstrate 5-year disease-free survival rate of 90–100%. Tumors extending beyond the renal capsule (T3 or T4) and node-positive tumors have 5-year disease-free survival rates of 50–60% and 0–15%, respectively. One subgroup of patients with nonlocalized disease has reasonable long-term survival, namely, those with solitary resectable metastases. In this setting, radical nephrectomy with resection of the solitary metastasis results in 5-year disease-free survival rate of 15–30%.

When to Refer

- Refer patients with solid renal masses or complex cysts to a urologist for further evaluation.
- Refer patients with renal cell carcinoma to a urologic surgeon for surgical excision.
- Refer patients with metastatic disease to an oncologist and urologist.

OTHER PRIMARY TUMORS OF THE KIDNEY

Oncocytomas account for 3–5% of renal tumors, are usually benign, and are indistinguishable from renal cell carcinoma on preoperative imaging. These tumors are seen in other organs, including the adrenals, salivary glands, and thyroid and parathyroid glands.

Angiomyolipomas are rare benign tumors composed of fat, smooth muscle, and blood vessels. They are most commonly seen in patients with tuberous sclerosis (often multiple and bilateral) or in young to middle-aged women. CT scanning may identify the fat component, which is diagnostic for angiomyolipoma. Asymptomatic lesions < 5 cm in diameter usually do not require intervention; large lesions can spontaneously bleed. Acute bleeding can be treated by angiographic embolization or, in rare cases, nephrectomy. Lesions over 5 cm are often prophylactically treated with angioembolization or less commonly partial nephrectomy to reduce the risk of bleeding. **Epithelioid angiomyolipoma** is a very rare acute myeloid leukemia (AML) subtype with malignant potential.

SECONDARY CANCERS OF THE KIDNEY

The kidney is a not infrequent site for metastatic disease. Of the solid tumors, lung cancer is the most common (20%), followed by breast (10%), stomach (10%), and the contralateral kidney (10%). Lymphoma, both Hodgkin and non-Hodgkin, may also involve the kidney, although it tends to appear as a diffusely infiltrative process resulting in renal enlargement rather than a discrete mass.

TESTICULAR CANCERS (Germ Cell Tumors)

ESSENTIALS OF DIAGNOSIS

- Most common neoplasm in men aged 20–35 years.
- Patient typically discovers a painless nodule.
- Orchiectomy necessary for diagnosis.

General Considerations

Malignant tumors of the testis are rare, with approximately five to six cases per 100,000 males reported in the United States each year. Ninety to 95 percent of all primary testicular tumors are germ cell tumors and can be divided into two major categories: **nonseminomas**, including embryonal cell carcinoma (20%), teratoma (5%), choriocarcinoma (< 1%), and mixed cell types (40%); and **seminomas** (35%). The remainder of primary testicular tumors are non-germ cell neoplasms (Leydig cell, Sertoli cell, gonadoblastoma). The lifetime probability of developing testicular cancer is 0.3% for an American male.

Approximately 5% of testicular cancers develop in a patient with a history of cryptorchism, with seminoma being the most common. However, 5–10% of these tumors occur in the contralateral, normally descended testis. The relative risk of development of malignancy is higher for the intra-abdominal testis (1:20) and lower for the inguinal testis (1:80). Placement of the cryptorchid testis into the scrotum (orchidopexy) does not alter its malignant potential but does facilitate routine examination and cancer detection.

Testicular cancer is slightly more common on the right than the left, paralleling the increased incidence of cryptorchidism on the right side. One to 2 percent of primary testicular cancers are bilateral and up to 50% of these men have a history of unilateral or bilateral cryptorchidism. Primary bilateral testicular cancers may occur synchronously or asynchronously but tend to be of the same histology. Seminoma is the most common histologic finding in bilateral *primary* testicular cancers, while malignant lymphoma is the most common bilateral testicular tumor overall.

In animal models, exogenous estrogen administration during pregnancy has been associated with an increased development of testicular tumors with relative risk ranging from 2.8 to 5.3. Other acquired factors such as trauma and infection-related testicular atrophy have been associated with testicular tumors; however, a causal relationship has not been established.

Clinical Findings

A. Symptoms and Signs

The most common symptom of testicular cancer is *painless enlargement of the testis*. Sensations of heaviness are not unusual. Patients are usually the first to recognize an abnormality, yet often their delay in seeking medical attention ranges from 3 to 6 months. Acute testicular pain resulting from intratesticular hemorrhage occurs in approximately 10% of cases. Ten percent of patients are asymptomatic at presentation, and 10% manifest symptoms relating to metastatic disease such as back pain (retroperitoneal metastases), cough (pulmonary metastases), or lower extremity edema (vena cava obstruction).

A discrete mass or a diffuse testicular enlargement is noted in most cases. Secondary hydroceles may be present in 5–10% of cases. In advanced disease, supraclavicular adenopathy may be present, and abdominal examination may reveal a mass. Gynecomastia is seen in 5% of germ cell tumors.

B. Laboratory Findings

Several serum markers are important in the diagnosis and monitoring of testicular carcinoma, including human chorionic gonadotropin (hCG), α-fetoprotein, and LD. α-Fetoprotein is never elevated with pure seminomas, and while hCG is occasionally elevated in seminomas, levels tend to be lower than those seen with nonseminomas. LD may be elevated with either type of tumor and is a marker for disease burden. Liver tests may be elevated in the presence of hepatic metastases, and anemia may be present in advanced disease.

C. Imaging

Scrotal ultrasound can readily determine whether a mass is intratesticular or extratesticular. Once the diagnosis of testicular cancer has been established by inguinal orchiectomy, clinical staging of the disease is accomplished by chest, abdominal, and pelvic CT scanning.

Staging

Testicular cancer is staged using the TNM system created based on extent of cancer in the testis, status of regional lymph nodes, the presence of metastases in distant lymph nodes or other viscera, and serum levels of tumor markers. Based on these features, germ cell tumors can be grouped to assign an overall stage: a stage I lesion is confined to the testis; a stage II lesion demonstrates regional lymph node involvement in the retroperitoneum; and a stage III lesion has distant metastasis.

Differential Diagnosis

An incorrect diagnosis is made at the initial examination in up to 25% of patients with testicular tumors. Scrotal ultrasonography should be performed if any uncertainty exists with respect to the diagnosis. Although most intratesticular masses are malignant, a benign lesion—epidermoid cyst—may rarely be seen. Epidermoid cysts are usually very small benign nodules located just underneath the tunica albuginea; occasionally, however, they can be large. Testicular lymphoma is discussed below.

Treatment

Inguinal exploration with early vascular control of the spermatic cord structures is the initial intervention. *If cancer cannot be excluded by examination of the testis, radical orchiectomy is warranted.* Scrotal approaches and open testicular biopsies should be avoided. Further therapy depends on the histology of the tumor as well as the clinical stage. Men treated for testis cancer are at risk for infertility and fertility preservation should be offered to all men with early referral to a specialist.

Patients with clinical stage I seminomas are candidates for surveillance (preferred), single-agent carboplatin, or adjuvant radiotherapy. Stage IIA and IIB seminomas (retroperitoneal disease < 2 cm diameter in IIA and 2–5 cm in IIB) are treated by radical orchiectomy plus retroperitoneal irradiation or primary systemic chemotherapy (etoposide and cisplatin or cisplatin, etoposide, and bleomycin) (Table 44–2). Seminomas of stage IIC (> 5-cm-diameter retroperitoneal nodes) and stage III receive primary systemic chemotherapy. After chemotherapy, surgical resection of residual retroperitoneal nodes is warranted if the node is > 3 cm in diameter and positive on PET scan, since 40% will harbor residual carcinoma.

Up to 75% of clinical stage I nonseminomas are cured by orchiectomy alone. Selected patients without specific risk factors have low risk of recurrence and are generally offered surveillance after orchiectomy. These selection criteria include (1) cancer is confined within the tunica albuginea; (2) cancer does not demonstrate vascular invasion; (3) tumor markers normalize after orchiectomy; (4) radiographic imaging of the chest and abdomen shows no evidence of disease; and (5) the patient is reliable. Patients most likely to experience relapse on a surveillance regimen include those with predominantly embryonal cancer and those with vascular or lymphatic invasion identified in the orchiectomy specimen. Alternatives to surveillance for clinical stage I nonseminomas include adjuvant chemotherapy (bleomycin, etoposide, cisplatin) (Table 44–2) or retroperitoneal lymph node dissection.

Following orchiectomy, patients with metastatic disease are typically treated with combination chemotherapy (cisplatin and etoposide or cisplatin, etoposide, and bleomycin) (Table 44–2). Low-volume metastatic disease can be offered retroperitoneal lymph node dissection for seminomatous and non-seminomatous germ cell tumors. The Surgery in Early Metastatic Seminoma trial demonstrated an 81% 2-year recurrence-free survival with low morbidity in men with low-volume retroperitoneal metastatic seminoma treated with surgery alone. Low-volume, metastatic seminoma can also be offered radiation therapy. Non-seminomatous tumors are not sensitive to radiation therapy. With metastatic non-seminomatous germ cell cancers, if tumor markers normalize but a residual mass > 1 cm persists on imaging studies, it should be referred for surgical resection since 15–20% will harbor residual cancer and 40% will harbor teratomas. If tumor markers fail to normalize following primary chemotherapy, salvage chemotherapy is required (cisplatin, etoposide, and ifosfamide).

Postoperative active surveillance by the clinician and patient means patients are followed up every 2–6 months for the first 2 years and every 4–6 months in the third year. For nonseminomas, tumor markers are obtained at each visit, and CXRs and abdominal and pelvic CT scans are obtained every 4–6 months. For seminomas, serum tumor markers may be obtained (optional), chest imaging is obtained only as clinically indicated, and abdominal and pelvic CT scans are performed every 3–6 months. Follow-up continues beyond the initial 3 years; however, 80% of relapses will occur within the first 2 years. With rare exceptions, patients who relapse can be cured by chemotherapy or surgery.

Prognosis

The 5-year disease-free survival rates for stage I and IIA seminomas (retroperitoneal disease < 2 cm in diameter) treated by radical orchiectomy and retroperitoneal irradiation are 98% and 92–94%, respectively. Ninety-five percent of patients with stage III disease attain a complete response following orchiectomy and chemotherapy. The 5-year disease-free survival rate for patients with stage I nonseminomas (includes all treatments) ranges from 96–100%. For low-volume stage II disease, a 5-year disease-free survival of 90% is expected. Patients with bulky retroperitoneal or disseminated disease treated with primary chemotherapy followed by surgery have a 5-year disease-free survival rate of 55–80%.

When to Refer

Refer all patients with solid masses of the testis to a urologist and a medical oncologist if metastatic disease is suspected.

Daneshmand S et al. Surgery in early metastatic seminoma: a phase II trial of retroperitoneal lymph node dissection for testicular seminoma with limited retroperitoneal lymphadenopathy. J Clin Onc. 2023;41:3009. [PMID: 36913642]

SECONDARY CANCERS OF THE TESTIS

Secondary cancers of the testis are rare. In men over the age of 50 years, lymphoma is the most common. Overall, it is the most common secondary neoplasm of the testis, accounting for 5% of all testicular cancers. It may be seen in three clinical settings: (1) late manifestation of widespread lymphoma, (2) the initial presentation of clinically occult disease, and (3) primary extranodal disease. Radical orchiectomy is indicated to make the diagnosis. Prognosis is related to the stage of disease.

Metastasis to the testis is rare. The most common primary site of origin is the prostate, followed by the lung, GI tract, melanoma, and kidney.

CANCER COMPLICATIONS & EMERGENCIES

SPINAL CORD COMPRESSION

ESSENTIALS OF DIAGNOSIS

- Complication of metastatic solid tumor, lymphoma, or plasma cell myeloma.
- Back pain is the most common presenting symptom.
- Prompt diagnosis is essential because once a severe neurologic deficit develops, it is often irreversible.
- Emergent treatment may prevent or potentially reverse paresis and urinary and bowel incontinence.

General Considerations

Cancers that cause spinal cord compression most commonly metastasize to the vertebral bodies, resulting in physical damage to the spinal cord from edema, hemorrhage, and pressure-induced ischemia to its vasculature. Persistent compression can result in irreversible changes to the myelin sheaths resulting in permanent neurologic impairment.

Prompt diagnosis and therapeutic intervention are essential. Patients who are treated promptly after symptoms appear may have partial or complete return of function and, depending on tumor sensitivity to specific treatment, may respond favorably to subsequent anticancer therapy.

Clinical Findings

A. Symptoms and Signs

Back pain at the level of the tumor mass occurs in over 80% of cases and may be aggravated by lying down, weight bearing, sneezing, or coughing; it usually precedes the development of neurologic symptoms or signs. Since involvement is usually epidural, a mixture of nerve root and spinal cord symptoms often develops. Progressive weakness and sensory changes commonly occur. Bowel and bladder symptoms progressing to incontinence are late findings.

The initial findings of impending cord compression may be quite subtle, and there should be a high index of suspicion when back pain or weakness of the lower extremities develops in a patient with cancer.

B. Imaging

MRI is usually the initial imaging procedure of choice in a patient with cancer and new-onset back pain. **When neurologic findings suggest spinal cord compression, an emergent MRI should be obtained**; the MRI should survey the entire spine to define all areas of tumor involvement for treatment planning purposes. MRI has a sensitivity of 93% and a specificity of 97% for diagnosis of metastatic spinal cord compression.

Treatment

Patients with a known cancer diagnosis found to have epidural impingement of the spinal cord should be given corticosteroids immediately. The initial dexamethasone dose is 10 mg intravenously followed by 4–6 mg every 6 hours intravenously or orally. Patients without a known diagnosis of cancer should have emergent surgery to relieve the impingement and obtain a pathologic specimen; preoperative corticosteroids should not be given since they might compromise the pathology results. Treatment planning requires consideration of spinal stability, radiosensitivity of tumor type, low- versus high-grade epidural spinal cord compression, and extent of multilevel involvement. *Patients with solid tumors who have a single area of compression and who are considered candidates for surgery are best treated first with surgical decompression followed by radiation therapy. If multiple vertebral body levels are involved with cancer, radiation therapy is the preferred treatment option.*

MALIGNANT EFFUSIONS

ESSENTIALS OF DIAGNOSIS

- Occur in pleural, pericardial, and peritoneal spaces.
- Caused by direct neoplastic involvement of serous surface or obstruction of lymphatic drainage.
- Half of undiagnosed effusions in patients not known to have cancer are malignant.

General Considerations

The development of an effusion in the pleural, pericardial, or peritoneal space may be the initial finding in a patient with cancer, or an effusion may appear during the course of disease progression. Direct involvement of the serous surface with tumor is the most frequent initiating cause of the accumulation of fluid. The most common malignancies causing pleural and pericardial effusions are lung and breast cancers; the most common malignancies associated with malignant ascites are ovarian, colorectal, stomach, and pancreatic cancers.

Clinical Findings

A. Symptoms and Signs

Patients with pleural and pericardial effusions complain of shortness of breath and orthopnea. Patients with ascites complain of abdominal distention and discomfort. Cardiac tamponade causing pressure equalization in the chambers impairs both filling and cardiac output and can be life-threatening. Signs of tamponade include tachycardia, muffled heart sounds, pulsus paradoxus, and hypotension. Signs of pleural effusions include decreased breath sounds, egophony, and percussion dullness.

B. Laboratory Findings

Malignancy is confirmed as the cause of an effusion when analysis of the fluid specimen shows malignant cells in either the cytology or cell block specimen. However, the diagnostic sensitivity of fluid cytology is often low, depending on the cancer type.

C. Imaging

The presence of effusions can be confirmed with radiographic studies or ultrasonography.

Differential Diagnosis

The differential diagnosis of a malignant pleural or pericardial effusion includes nonmalignant processes, such as infection, PE, HF, and trauma. The differential diagnosis of malignant ascites includes similar benign processes, such as HF, cirrhosis, peritonitis, and pancreatic ascites. Bloody effusions are usually due to cancer, but a bloody pleural effusion can also be due to PE, trauma and, occasionally, infection. Chylous pleural or ascitic fluid is generally associated with obstruction of lymphatic drainage as might occur in lymphoma.

Treatment

The development of a malignant effusion is a late-stage manifestation of the cancer. Treatment is tailored to the underlying cancer, whether with targeted therapy, chemotherapy, or immunotherapy, depending on tumor testing results. Effective systemic treatment can lead to regression of the effusion. Acute symptoms related to the effusion often require urgent intervention with drainage of the effusion. Decisions regarding palliative management of malignant effusion are in large part dictated by the patient's symptoms and goals of care.

A. Pleural Effusion

A pleural effusion that is symptomatic may be managed initially with a *large-volume thoracentesis*. In some patients, the effusion slowly reaccumulates, which allows for periodic thoracentesis when the patient becomes symptomatic. However, in many patients, the effusion reaccumulates quickly, causing rapid return of shortness of breath. For those patients, two management options exist: *pleurodesis* or *indwelling pleural catheter* (eg, PleurX). In a meta-analysis of RCTs comparing indwelling pleural catheter with pleurodesis, indwelling pleural catheters resulted in shorter hospital stays and fewer repeat pleural interventions, but increased rates of cellulitis.

B. Pericardial Effusion

Fluid may be removed by needle aspiration or by placement of a catheter for more thorough drainage. As with pleural effusions, most pericardial effusions will reaccumulate. Management options for recurrent, symptomatic effusions include prolonged *catheter drainage* or surgical intervention such as a *pericardiotomy or pericardiectomy.*

C. Malignant Ascites

Patients with malignant ascites not responsive to chemotherapy are generally treated with *repeated large-volume paracenteses.* Since the frequency of drainage to maintain comfort can compromise the patient's quality of life, other alternatives include placement of a *catheter or port* so that the patient or caregiver can drain fluid as needed at home. For patients with portal hypertension from large hepatic masses, *diuretics* may be useful to decrease the need for repeated paracentesis.

HYPERCALCEMIA

ESSENTIALS OF DIAGNOSIS

- Most common paraneoplastic endocrine syndrome.
- Usually symptomatic and severe (≥ 15 mg/dL [3.75 mmol/L]); accounts for most inpatients with hypercalcemia.
- The neoplasm is clinically apparent in nearly all cases when hypercalcemia is detected.

General Considerations

Hypercalcemia affects 20–30% of patients with cancer at some point during their illness. The most common cancers causing hypercalcemia are myeloma, breast carcinoma, and NSCLC. Hypercalcemia is caused by one of three mechanisms: systemic effects of tumor-released proteins, direct osteolysis of bone by tumor, or vitamin D–mediated osteoabsorption.

Clinical Findings

A. Symptoms and Signs

Symptoms and signs of hypercalcemia can be subtle; more severe symptoms occur with higher levels of hypercalcemia and with a rapidly rising calcium level. Early symptoms typically include anorexia, nausea, fatigue, constipation, and polyuria; later findings may include muscular weakness and hyporeflexia, confusion, psychosis, tremor, and lethargy.

B. Laboratory Findings

Symptoms and signs are caused by free calcium; as calcium is bound by protein in the serum, *the measured serum calcium will underestimate the free or ionized calcium in patients with low albumin levels.* Free ionized calcium can be measured. When the corrected serum calcium rises above 12 mg/dL (3 mmol/L), especially if the rise occurs rapidly, sudden death due to cardiac arrhythmia or asystole may occur. Initial workup for hypercalcemia includes obtaining serum PTH, PTHrP, and calcitriol (1,25-dihydroxycholecalciferol) levels.

C. ECG

ECG in hypercalcemia often shows a shortening of the QT interval.

Treatment

Emergency management should begin with the initiation of *intravenous fluids* with 0.9% saline at 100–300 mL/h to ensure rehydration with brisk urinary output of the often volume-depleted patient. For moderate or severe hypercalcemia, treatment with *bisphosphonate* or *denosumab* (humanized monoclonal antibody to RANKL) is indicated. Bisphosphonates can be given if kidney function is normal or only marginally impaired. Choices include pamidronate or zoledronic acid. Denosumab is also the preferred choice for the management of bisphosphonate-refractory hypercalcemia or for patients with kidney dysfunction. Once hypercalcemia is controlled, treatment directed at the cancer should be initiated if possible. If hypercalcemia becomes refractory to bisphosphonates or denosumab, other agents include *calcitonin* or *corticosteroids*. Salmon calcitonin can be used in patients with severe, symptomatic hypercalcemia.

Walker MD et al. Hypercalcemia: a review. JAMA. 2022;328:1624. [PMID: 36282253]

HYPERURICEMIA & TUMOR LYSIS SYNDROME

ESSENTIALS OF DIAGNOSIS

- Complication of treatment-associated tumor lysis of hematologic and rapidly proliferating malignancies.
- May be worsened by thiazide diuretics.
- Rapid increase in serum uric acid can cause acute urate nephropathy from uric acid crystallization.
- Reducing pre-chemotherapy serum uric acid is fundamental to preventing urate nephropathy.

General Considerations

Tumor lysis syndrome (TLS) is seen most commonly following treatment of hematologic malignancies but can develop from any tumor highly sensitive to chemotherapy. TLS is caused by the massive release of cellular material including nucleic acids, proteins, phosphorus, and potassium. If both the metabolism and excretion of these breakdown products are impaired, hyperuricemia, hyperphosphatemia, and hyperkalemia will develop abruptly. AKI may then develop from the crystallization and deposition of uric acid and calcium phosphate within the renal tubules, further exacerbating the hyperphosphatemia and hyperkalemia.

Clinical Findings

A. Symptoms and Signs

Symptoms of hyperphosphatemia include nausea, vomiting, anorexia, muscle cramps, tetany, and seizures. High levels of phosphorus and co-precipitation with calcium can cause renal tubule blockage, further exacerbating the kidney injury. Hyperkalemia, due to release of intracellular potassium and impaired kidney excretion, can cause arrhythmias and sudden death.

B. Laboratory Findings

The laboratory diagnosis of TLS includes at least two of the following criteria observed within a 24-hour period: uric acid 8 mg/dL or higher (476 mcmol/L or higher), phosphate 4.5 mg/dL or higher (1.45 mmol/L or higher), potassium 6.0 mEq/L or more (6 mmol/L or more) (or a 25% increase from baseline for these parameters), and corrected serum calcium 7 mg/dL or lower (1.75 mmol/L or lower). A clinical diagnosis of TLS includes meeting the laboratory criteria and at least one clinical criterion: AKI (creatinine ≥ 1.5 × upper limit of normal or increase > 0.3 g/dL or cardiac arrhythmia, sudden cardiac death, or seizure.

Treatment

Prevention is the most important factor in the management of TLS. Aggressive hydration at least 24 hours prior to chemotherapy as well as 24–48 hours after chemotherapy completion helps keep urine flowing and facilitates excretion of uric acid and phosphorus. It is recommended to maintain a urinary output of at least 100 mL/hour, and a daily urine volume of at least 3 L/day. For patients at moderate risk of developing TLS, eg, those with intermediate-grade lymphomas and acute leukemias, allopurinol should be given before starting chemotherapy with dose reductions for impaired kidney function. Rasburicase also is given intravenously to patients at high risk for developing TLS such as those with high-grade lymphomas or acute leukemias with markedly elevated WBC counts. Rasburicase cannot be given to patients with known glucose 6-phosphate dehydrogenase (G6PD) deficiency nor can it be given to pregnant or lactating women.

When to Refer

- Should urinary output drop, serum creatinine or potassium levels rise, or hyperphosphatemia persist, a nephrologist should be immediately consulted to evaluate the need for dialysis.

INFECTIONS

Chapters 35 and 36 provide more detailed discussions of infections in the immunocompromised patient.

ESSENTIALS OF DIAGNOSIS

- In patients with neutropenia, infection is a medical emergency.
- Although sometimes attributable to other causes, the presence of fever, defined as a single temperature > 38.3°C (101°F) or a temperature of > 38°C (100.4°F) for > 1 hour, must be assumed to be due to an infection.

General Considerations

Many patients with disseminated neoplasms have increased susceptibility to infection. In some patients, this results from impaired defense mechanisms (eg, acute leukemia, Hodgkin lymphoma, myeloma, chronic lymphocytic leukemia); in others, it results from the myelosuppressive and immunosuppressive effects of cancer chemotherapy or a combination of these factors. Patients with cancer are at higher risk for infection with SARS-CoV-2, with more severe cases of COVID-19 infection and complications.

The source of a neutropenic febrile episode is determined in about 30% of cases through blood, urine, or sputum cultures. The bacterial organisms accounting for most infections in patients with cancer include gram-positive bacteria and gram-negative bacteria. Gram-positive organism infections are more common, but gram-negative infections are more serious and life-threatening. The risk of bacterial infections rises when the neutrophil count is below 500/mcL (0.5 × 10^9/L); the risk markedly increases when the count falls below 100/mcL (0.1 × 10^9/L) or when there is a prolonged duration of neutropenia, typically > 7 days.

Clinical Findings

A thorough physical examination should be performed. Appropriate cultures (eg, blood, sputum, urine and, if indicated, CSF) and COVID-19 testing should always be obtained. Two sets of blood cultures should be drawn before starting antibiotics; if the patient has an indwelling catheter, one of the cultures should be drawn from the line. A CXR should also be obtained.

Treatment

Empiric antibiotic therapy needs to be initiated within 1 hour of presentation and following the collection of blood cultures in the febrile neutropenic patient. The choice of antibiotics depends on a number of different factors including the patient's clinical status and any localizing source of infection. If the patient is clinically well, monotherapy with an intravenous β-lactam with anti-*Pseudomonas* activity (cefepime, ceftazidime, imipenem/cilastatin, piperacillin/tazobactam) should be started (see Infections in the Immunocompromised Patient, Chapter 35). If the patient is clinically ill with hypotension or hypoxia, an intravenous aminoglycoside or fluoroquinolone should be added for "double" gram-negative bacteria coverage. If there is a strong suspicion of a gram-positive organism, such as from a *S aureus* catheter infection, intravenous vancomycin can be given empirically. Low-risk patients may be treated with oral antibiotics in the outpatient setting.

Antibiotics should be continued until the neutrophil count is rising and > 500/mcL (0.5 × 10^9/L) for at least 1 day and the patient has been afebrile for 2 days. If an organism is identified through the cultures, the antibiotics should be adjusted to the antibiotic sensitivities of the isolate; treatment should be continued for the appropriate period of time and at least until the neutrophil count recovers and fever resolves.

PRIMARY CANCER TREATMENT

SYSTEMIC CANCER THERAPY

Detailed guidelines from the NCCN for cancer treatment can be found at www.nccn.org.

Use of cytotoxic medications, immunotherapy, hormones, antihormones, and biologic agents has become a highly specialized and increasingly effective means of treating cancer, with therapy administered and monitored by a medical oncologist or hematologist. Selection of specific medications or protocols for various types of cancer is based on results of clinical trials. Increasingly, agents are being identified that target specific molecular pathways or modulate the immune system. Initial and acquired drug resistance remains a challenge. Described mechanisms of drug resistance include impaired membrane transport of drugs, enhanced drug metabolism, mutated target proteins, and blockage of apoptosis due to mutations in cellular proteins (see Table 44–2 for suggested agents for various cancers).

TOXICITY & DOSE MODIFICATION OF CHEMOTHERAPEUTIC AGENTS

Use of chemotherapy to treat cancer is generally guided by results from clinical trials in individual tumor types. Medication side effects and toxicities must be anticipated and carefully monitored. The short- and long-term toxicities of individual medications are listed in Tables 44–3 and 44–16. In the palliative setting where the aim of therapy is to improve symptoms and quality of life, lowering doses to minimize toxicity is commonly done. However, when the goal of treatment is cure, dosing frequency and intensity should be maintained whenever possible.

A CBC including a differential count, with absolute neutrophil count and platelet count, and liver and kidney tests should be obtained before the initiation of chemotherapy and at regular intervals. *When the intent of chemotherapy is cure, including treatment in the adjuvant setting, every attempt should be made to schedule chemotherapy on time and at full dose.* A schema for dose modification is shown in Table 44–17.

1. Bone Marrow Toxicity

A. Neutropenia

Granulocyte colony-stimulating factor (G-CSF), given as either daily subcutaneous injections (eg, filgrastim, 300 mcg or 480 mcg) or as a one-time dose (pegfilgrastim, 6 mg) after cytotoxic chemotherapy is completed, reduces the duration and severity of granulocytopenia following cytotoxic chemotherapy (Table 44–16). The American Society of Clinical Oncology and NCCN guidelines recommend primary prophylaxis with G-CSF when there is at least a 20% risk of febrile neutropenia or when age, medical history, and disease characteristics put the patient at high risk for complications related to myelosuppression.

B. Anemia

Erythropoiesis-stimulating agents ameliorate the anemia and its associated symptoms caused by cancer chemotherapy but these medications have untoward effects, including an increased risk of thromboembolism, and possibly a decreased survival due to cancer-related deaths as well as a shortened time to tumor progression. The FDA recommends that these medications should *not* be used when the intent of chemotherapy is curative. Administration of RBC transfusions is an alternative for managing symptomatic anemia in chemotherapy patients.

Erythropoiesis-stimulating agents can be an option in patients with cancer and symptomatic anemia undergoing palliative treatment; patient preference is important in determining when to use erythropoiesis-stimulating agents or transfusions. When using erythropoiesis-stimulating agents, treatment should not be initiated until the hemoglobin is < 10 g/dL (100 g/L) and the agent held when the hemoglobin is > 12 g/dL (120 g/L). To have maximum therapeutic effect, patients need to be iron replete.

Table 44–16. Commonly used supportive care agents[1] (listed in alphabetical order, with categories).

Agent	Indication	Usual Dose	Adverse Effects
Bone-Modifying Agents			
Denosumab (Xgeva)	Osteolytic bone metastasis	120 mg subcutaneously every 4 weeks	Acute: nausea Delayed: hypocalcemia, hypophosphatemia, fatigue, osteonecrosis of the jaw
Zoledronic acid (Zometa)	Osteolytic bone metastasis, hypercalcemia of malignancy	4 mg intravenously every 3–4 weeks; 4 mg intravenously once, may repeat after 7 days	Acute: nausea Delayed: dyspnea, arthralgia, bone pain, osteonecrosis of the jaw, nephrotoxicity, hypocalcemia
Growth Factors			
Darbepoetin alfa (Aranesp)	Chemotherapy-induced anemia	2.25 mcg/kg subcutaneously weekly; 500 mcg subcutaneously every 3 weeks	Acute: injection site reaction Delayed: hypertension, thromboembolic events, increased risk of tumor progression or recurrence
Epoetin alfa (Epogen, Procrit)	Chemotherapy-induced anemia	40,000 U subcutaneously once weekly; 150 U/kg subcutaneously three times a week	Acute: injection site reaction Delayed: hypertension, thromboembolic events, increased risk of tumor progression or recurrence
Filgrastim (Neupogen)	Febrile neutropenia prophylaxis, mobilization of peripheral stem cells	5–10 mcg/kg/day subcutaneously or intravenously once daily, treat past nadir	Acute: injection site reaction Delayed: bone pain
Pegfilgrastim (Neulasta)	Febrile neutropenia prophylaxis	6 mg subcutaneously once per chemotherapy cycle	Acute: injection site reaction Delayed: bone pain
Miscellaneous Agents			
Allopurinol (Xyloprim)	Prevent hyperuricemia from tumor lysis syndrome	600–800 mg/day orally	Acute: none Delayed: rash
Leucovorin	Rescue after high-dose methotrexate; in combination with 5-fluorouracil for colon cancer	10 mg/m^2 intravenously or orally every 6 hours; 20 mg/m^2 or 200–500 mg/m^2 intravenously before 5-fluorouracil; various doses	Acute: nausea, vomiting, diarrhea Delayed: stomatitis, fatigue
Mesna (Mesnex)	Prevent ifosfamide-induced hemorrhagic cystitis	20% of ifosfamide dose intravenously at 0, 4, and 8 hours; various doses	Acute: nausea, vomiting Delayed: fatigue
Rasburicase (Elitek)	Prevent hyperuricemia from tumor lysis syndrome	3–6 mg intravenously once	Acute: hypersensitivity, nausea, vomiting, diarrhea, fever, headache Delayed: rash, peripheral edema

[1] For amifostine, levoleucovorin, pilocarpine, samarium, strontium, pamidronate, sargramostim, dexrazoxane, palifermin, radium, filgrastim-sndz, and tbo-filgrastim, see Table 44–16 in *CMDT Online* at www.accessmedicine.com.

Table 44–17. A common schema for dose modification of cancer chemotherapeutic agents.

Granulocyte Count	Platelet Count	Suggested Drug Dosage (% of Full Dose)
> 2000 cells/mcL (2×10^9/L)	> 100,000/mcL (100×10^9/L)	100%
1000–2000 cells/mcL ($1–2 \times 10^9$/L)	75,000–100,000/mcL ($75–100 \times 10^9$/L)	50%
< 1000 cells/mcL (1×10^9/L)	< 50,000/mcL (50×10^9/L)	0%

C. Thrombocytopenia

Pharmacologic management of chemotherapy-induced thrombocytopenia is more limited. Two medications that activate the thrombopoietin receptor, romiplostim and eltrombopag, are FDA-approved only for use in idiopathic thrombocytopenia, thrombocytopenia related to interferon therapy of hepatitis C, and thrombocytopenia in aplastic anemia.

2. Chemotherapy-Induced Nausea & Vomiting

Several cytotoxic anticancer medications can induce nausea and vomiting, which can be the most anticipated and stressful side effects for patients. Chemotherapy-induced nausea and vomiting is mediated in part by the stimulation of at least two CNS receptors, 5-hydroxytryptamine subtype 3 ($5HT_3$) and neurokinin subtype 1 (NK_1). Chemotherapy-induced nausea and vomiting can be *anticipatory*, occurring even before chemotherapy administration; *acute*, occurring within minutes to hours of chemotherapy administration; or *delayed,* lasting up to 7 days. *Chemotherapy drugs are classified into high, moderate, low, and minimal likelihoods of causing emesis.* Highly emetogenic chemotherapy medications include cisplatin, cyclophosphamide (at doses over 1.5 g/m^2), and anthracyclines. Moderately emetogenic chemotherapy drugs include azacitidine, carboplatin, cytarabine, and oxaliplatin. Low emetogenic medications include bortezomib, etoposide, gemcitabine, methotrexate, and paclitaxel. Medications with minimal risk of emesis include bevacizumab, cetuximab, rituximab, and trastuzumab.

Major advances have occurred in the development of highly effective antiemetic drugs. Antagonists to the $5HT_3$-receptor include alosetron, granisetron, ondansetron, and palonosetron. Ondansetron can be given either intravenously (8 mg or 0.15 mg/kg) or orally. Dosing of granisetron is 1 mg or 0.01 mg/kg intravenously or 1–2 mg orally. Palonosetron, a long-acting $5HT_3$-receptor antagonist with high affinity for the receptor, is given once at a dose of 0.25 mg intravenously, both for acute and delayed emesis. As a class of drugs, the $5HT_3$-receptor antagonists have the potential to cause ECG changes, including QT prolongation.

Antagonists to the NK_1-receptor are aprepitant, fosaprepitant, and netupitant. Aprepitant is given as a 125-mg oral dose followed by an 80-mg dose on the second and third day along with a $5HT_3$-receptor antagonist and dexamethasone to increase its immediate and delayed protective effect for highly emetogenic chemotherapy. Fosaprepitant, the intravenous formulation of the prodrug to aprepitant, can be given at a dose of 115 mg if followed by 2 days of aprepitant or at a dose of 150 mg if given alone.

For highly emetogenic chemotherapy (eg, cisplatin), patients should be offered a four-drug regimen (a $5HT_3$-antagonist, dexamethasone, NK_1-receptor antagonist, and olanzapine), all given on the first day. For moderately emetogenic chemotherapy, standard regimens include both three-drug regimens (an NK_1-antagonist, a $5HT_3$-antagonist, and dexamethasone) or a two-drug combination ($5HT_3$-antagonist and dexamethasone). For low emetogenic chemotherapy drugs, a single agent such as a $5HT_3$-antagonist or prochlorperazine or dexamethasone can be given. Olanzapine, 10 mg given orally once, is helpful for anticipatory or refractory nausea and vomiting.

The importance of treating chemotherapy-induced nausea and vomiting expectantly and aggressively beginning with the first course of chemotherapy cannot be overemphasized. Patients being treated in the clinic setting should always be given antiemetics for home use with written instructions as well as contact numbers to call for advice.

3. Gastrointestinal Toxicity

Untoward effects of cancer chemotherapy include damage to the more rapidly growing cells of the body such as the mucosal lining from the mouth through the GI tract. Oral symptoms range from mild mouth soreness to frank ulcerations. Not uncommonly, mouth ulcerations will have superimposed candida or herpes simplex infections. In addition to receiving cytotoxic chemotherapy, a significant risk factor for development of oral mucositis is poor oral hygiene and existing caries or periodontal disease. Patients undergoing treatment for head and neck cancer with concurrent chemotherapy and radiation therapy have a very high risk of developing severe mucositis. Toxicity in the GI tract usually manifests as diarrhea. GI symptoms can range from mild symptoms of loose stools to life-threatening diarrhea leading to dehydration and electrolyte imbalances. Medications most commonly associated with causing mucositis in the mouth and the GI tract are cytarabine, 5-fluorouracil, and methotrexate.

Preventive strategies for oral mucositis include pretreatment dental care, particularly for all patients with head and neck cancer and any patient with cancer and poor dental hygiene who will be receiving chemotherapy. Once mucositis is encountered, superimposed fungal infections should be treated with topical antifungal medications or systemic therapy. Suspected herpetic infections can be treated with acyclovir or valacyclovir. Mucositis may also be managed with mouthwashes; it is also important to provide adequate pain medication.

Diarrhea is most associated with 5-fluorouracil, capecitabine, and irinotecan as well as the tyrosine kinase inhibitors (dasatinib, imatinib, sorafenib, sunitinib) and epithelial growth factor inhibitors (cetuximab, erlotinib). Mild to moderate diarrhea due to cytotoxic chemotherapy not related to immunotherapy, can be managed with oral antidiarrheal medication. Occasionally, severe diarrhea will cause dehydration, electrolyte imbalances, and AKI; these patients require inpatient management with aggressive intravenous hydration and electrolyte replacement. Diarrhea associated with checkpoint inhibitors is concerning for immune-related colitis and warrants workup to rule out infection. Consider a referral to a gastroenterologist for colonoscopy, an abdominal CT scan, and a trial of corticosteroids for grade 2 and higher diarrhea. Consider permanent discontinuation of the checkpoint inhibitor for grade 3 and higher diarrhea, especially any one of the CTLA-4 inhibitors.

4. Miscellaneous Drug-Specific Toxicities

The toxicities of individual drugs are summarized in Tables 44–3 and 44–16; however, several of these toxicities warrant additional mention, since they occur with frequently administered agents, and special measures are often indicated.

A. Hemorrhagic Cystitis Induced by Cyclophosphamide or Ifosfamide

Patients receiving cyclophosphamide or ifosfamide must maintain a high fluid intake prior to and following the administration of the medication and be counseled to empty their bladders frequently. Early symptoms suggesting bladder toxicity include dysuria and increased frequency of urination. Should microscopic hematuria develop, it is advisable to stop the drug temporarily or switch to a different alkylating agent, to increase fluid intake, and to administer a urinary analgesic such as phenazopyridine. The neutralizing agent, mesna, can be used for patients in whom cystitis develops. With severe cystitis, large segments of bladder mucosa may be shed, resulting in prolonged gross hematuria. Such patients should be observed for signs of urinary obstruction and may require cystoscopy for removal of obstructing blood clots.

B. Neuropathy Due to Vinca Alkaloids and Other Chemotherapy Drugs

Neuropathy is caused by a number of different chemotherapy medications, the most common being vincristine. The peripheral neuropathy can be sensory, motor, autonomic, or a combination of these types. In its mildest form, it consists of paresthesias of the fingers and toes. With continued vincristine therapy, the paresthesias extend to the proximal interphalangeal joints, hyporeflexia appears in the lower extremities, and significant weakness can develop. Other drugs in the vinca alkaloid class as well as the taxane drugs (docetaxel and paclitaxel) and agents to treat myeloma (bortezomib and thalidomide) cause similar toxicity.

Constipation is the most common symptom of autonomic neuropathy associated with the vinca alkaloids. Patients receiving these medications should be started on mild cathartics (eg, senna and polyethylene glycol [MiraLAX]) and other agents (see Table 17–4); otherwise, severe impaction may result from an atonic bowel.

C. Methotrexate Toxicity

Methotrexate, a folate antagonist, is a commonly used component of regimens to treat patients with leptomeningeal disease, acute lymphoblastic leukemia, and sarcomas. Methotrexate is almost entirely eliminated by the kidney. Methotrexate toxicity affects cells with rapid turnover, including the bone marrow and mucosa resulting in myelosuppression and mucositis. High-dose methotrexate, usually defined as a dose of 500 mg/m^2 or more given over 4–36 hours, would be lethal without "rescue" of the normal tissues. Leucovorin, a form of folate, will reverse the toxic effects of methotrexate and is given until serum methotrexate levels are in the safe range (< 0.05 mmol/L). *It is crucial that high-dose methotrexate and leucovorin are given precisely according to protocol as deviations of the timing of methotrexate delivery or delay in rescue can result in death.*

D. Cardiotoxicity from Anthracyclines and Other Chemotherapy Drugs

A number of cancer medications are associated with cardiovascular complications, including (1) traditional chemotherapeutics (such as anthracyclines); (2) HER2 inhibitors (such as pertuzumab, trastuzumab); (3) VEGF signaling pathway inhibitors (such as bevacizumab, lenvatinib, ramucirumab, sunitinib); (4) multitargeted tyrosine kinase inhibitors (such as dasatinib, nilotinib); (5) proteasome inhibitors (bortezomib, carfilzomib); and (6) immune checkpoint inhibitors (atezolizumab, ipilimumab, nivolumab, pembrolizumab).

The anthracycline medications can produce acute, subacute (days to months following administration), and delayed (years following administration) cardiac toxicity. *The most feared complication is the delayed development of HF. Patients receiving anthracyclines should have an assessment of LVEF.* If the LVEF is > 50%, anthracyclines can be administered; if the LVEF is < 30%, these medications should not be given. For patients with intermediate values, anthracyclines can be cautiously given, if necessary, at lower doses with LVEF monitoring between doses. In general, patients should not receive doses in excess of 450 mg/m^2.

E. Cisplatin Nephrotoxicity and Neurotoxicity

Cisplatin is effective in treating testicular, bladder, head and neck, lung, and ovarian cancers. With cisplatin, the serious side effects of nephrotoxicity and neurotoxicity must be anticipated and aggressively managed. Patients must be vigorously hydrated prior to, during, and after cisplatin administration. Both kidney function and electrolytes must be monitored. The neurotoxicity is usually manifested as a peripheral neuropathy of mixed sensorimotor type and may be associated with painful paresthesias. Ototoxicity is a potentially serious manifestation of neurotoxicity and can progress to deafness. The second-generation platinum analog carboplatin is non-nephrotoxic, although it is myelosuppressive. In the setting of preexisting kidney disease or neuropathy, carboplatin can be substituted for cisplatin for some indications.

F. Immune Checkpoint Inhibitor–Associated Toxicity

Cancer immunotherapy has revolutionized cancer care. The modalities of cancer immunotherapeutics include checkpoint inhibition, adoptive cellular therapy, and cancer vaccines. As an example, consider checkpoint inhibition. Checkpoint inhibitors include PD-1 inhibitors such as pembrolizumab, nivolumab, cemiplimab and dostarlimab, and PD-L1 inhibitors such as atezolizumab, avelumab, and durvalumab. The PD-1 pathway limits the immune response through inhibitory intracellular signaling in effector and regulatory T cells and induces T-cell exhaustion. Thus, inhibitors of PD-1 or PD-L1 release T cells from the inhibitory signals they receive from tumor cells via the PD-1 pathway, restoring antitumor immunity. Cytotoxic T lymphocyte antigen 4 (CTLA4) is another negative regulator of T-cell activation. Ipilimumab is a recombinant human IgG1 immunoglobulin monoclonal antibody to CTLA4. CTLA4 blockade by ipilimumab results in T-cell activation and proliferation, and enhanced antitumor activity. Checkpoint inhibitors play key roles in multiple types of cancer, including melanoma, lung, bladder, kidney, esophageal, and triple-negative breast cancers.

Checkpoint inhibition, however, can lead to significant **immunotherapy-related adverse events (irAEs).** Autoimmune damage can occur in any organ or system of the body. *The most common irAEs include thyroiditis, dermatitis, colitis, hepatitis, and arthritis. Pneumonitis is an uncommon but serious irAE.* Grading of AEs is based on Common Terminology Criteria for Adverse Events (CTCAE). Mild grade 1 toxicities can be followed except for certain neurologic, hematologic, and cardiac toxicities. For grade 2 or higher irAEs, checkpoint inhibitors are held until resolution of the adverse event, and depending on the severity of the irAE, may need to be permanently discontinued. Rarely, fulminant and life-threatening toxicities can occur. Glucocorticoids are the mainstay in management of irAEs, and if the event is refractory to steroids, infliximab and other immunosuppressive agents can be employed.

PROGNOSIS

Patients receiving therapy for curative intent will often tolerate side effects with the knowledge that the treatment may result in eradication of their cancer. Patients receiving therapy for palliative intent often have their therapy tailored to improve quality of life while minimizing major side effects. A valuable sign of clinical improvement is the *general well-being* of the patient.

Genetic & Genomic Disorders

Reed E. Pyeritz, MD, PhD

ACUTE INTERMITTENT PORPHYRIA

ESSENTIALS OF DIAGNOSIS

- Unexplained abdominal crisis, generally in young women.
- Acute peripheral or CNS dysfunction; recurrent psychiatric illnesses.
- Hyponatremia.
- Porphobilinogen in the urine during an attack.

General Considerations

Though there are several different types of porphyrias, the one with the most serious consequences and that usually presents in adulthood is acute intermittent porphyria (AIP), which is inherited as an autosomal dominant condition, though it remains clinically silent in most patients who carry a pathogenic variant in *HMBS*. Clinical illness usually develops in women. Symptoms begin in the teens or 20s, but onset can begin after menopause in rare cases. The disorder is caused by partial deficiency of hydroxymethylbilane synthase activity, leading to increased excretion of aminolevulinic acid and porphobilinogen in the urine. The diagnosis may be elusive if not specifically considered. *The characteristic abdominal pain may be due to abnormalities in autonomic innervation in the gut*. In contrast to other forms of porphyria, cutaneous photosensitivity is absent in AIP. Attacks are precipitated by numerous factors, including drugs and intercurrent infections. Hyponatremia may occur, due in part to inappropriate release of ADH, although GI loss of sodium in some patients may be a contributing factor.

Clinical Findings

A. Symptoms and Signs

Patients show intermittent abdominal pain of varying severity, and in some instances, it may so simulate an acute abdomen as to lead to exploratory laparotomy. Because the origin of the abdominal pain is neurologic, there is an absence of fever and leukocytosis. Complete recovery between attacks is usual. Any part of the nervous system may be involved, with evidence for central, autonomic, and peripheral neuropathy. Peripheral neuropathy may be symmetric or asymmetric and mild or profound; in the latter instance, it can even lead to quadriplegia with respiratory paralysis. Other CNS manifestations include seizures, altered consciousness, psychosis, and abnormalities of the basal ganglia. Hyponatremia may further cause or exacerbate CNS manifestations.

B. Laboratory Findings

Often there is profound hyponatremia. *The diagnosis can be confirmed by demonstrating an increased amount of porphobilinogen in the urine during an acute attack*. Freshly voided urine is of normal color but may turn dark upon standing in light and air.

Most families have different pathogenic variants in *HMBS* causing AIP. These variants can be detected in about 90% of patients and used for presymptomatic and prenatal diagnosis.

Prevention

Avoidance of factors known to precipitate attacks of AIP—especially medications—can reduce morbidity. Sulfonamides and barbiturates are the most common culprits; others are listed in Table 45–1 and online at https://porphyriafoundation.org/for-patients/about-porphyria/treatment-options/. Starvation diets and prolonged fasting also cause attacks and so must be avoided. Hormonal changes during pregnancy can precipitate crises.

Treatment

Treatment with a high-carbohydrate diet diminishes the number of attacks in some patients and is a reasonable empiric gesture considering its benignity. A minimum of 300 g of carbohydrates per day should be provided orally or intravenously. Acute attacks may be life-threatening and require prompt diagnosis, withdrawal of the inciting agent (if possible), and treatment with analgesics and

Table 45–1. Some of the "unsafe" and "probably safe" medications used in the treatment of acute porphyrias (listed in alphabetical order, within categories).

Unsafe	Probably Safe
Alcohol	Acetaminophen
Alkylating agents	Amitriptyline
Barbiturates	Aspirin
Carbamazepine	Atropine
Chloroquine	β-Adrenergic blockers
Chlorpropamide	Chloral hydrate
Clonidine	Chlordiazepoxide
Dapsone	Corticosteroids
Ergots	Diazepam
Erythromycin	Digoxin
Estrogens, synthetic	Diphenhydramine
Food additives	Guanethidine
Glutethimide	Hyoscine
Griseofulvin	Ibuprofen
Hydralazine	Imipramine
Ketamine	Insulin
Meprobamate	Lithium
Methyldopa	Naproxen
Metoclopramide	Nitrofurantoin
Nortriptyline	Opioid analgesics
Pentazocine	Penicillamine
Phenytoin	Penicillin and derivatives
Progestins	Phenothiazines
Pyrazinamide	Procaine
Rifampin	Streptomycin
Spironolactone	Succinylcholine
Succinimides	Tetracycline
Sulfonamides	Thiouracil
Theophylline	
Tolazamide	
Tolbutamide	
Valproic acid	

intravenous glucose in saline. Electrolyte balance requires close attention. Hemin therapy has been used but with serious adverse effects, especially phlebitis and coagulopathy. Givosiran, a δ aminolevulinic acid synthase-directed small interfering RNA, is standard of care. This medication reduces attacks and the need for hemin use; it requires monthly subcutaneous administration. Liver transplantation is an option for patients with disease poorly controlled by medical therapy.

When to Refer

- For management of severe abdominal pain, seizures, or psychosis.
- For preventive management when a patient with porphyria considers becoming pregnant.
- For genetic counseling and molecular diagnosis.

When to Admit

For an acute attack when accompanied by mental status changes, seizure, or hyponatremia.

DOWN SYNDROME

ESSENTIALS OF DIAGNOSIS

- Typical craniofacial features (flat occiput, epicanthal folds, large tongue).
- Intellectual disability.
- Congenital heart disease (eg, atrioventricular canal defects) in 50% of patients.
- Three copies of chromosome 21 (trisomy 21) or a chromosome rearrangement that results in three copies of a region of the long arm of chromosome 21.

General Considerations

Nearly 0.5% of all human conceptions are trisomic for chromosome 21. Because of increased fetal mortality, birth incidence of Down syndrome is 1 per 700 but varies from 1 per 1000 in young mothers to more than three times as frequent in women of advanced maternal age. The presence of a fetus with Down syndrome can be detected in many pregnancies in the first or early second trimester through screening maternal serum for *α-fetoprotein* and other biomarkers ("multiple marker screening") and by detecting increased nuchal thickness and underdevelopment of the nasal bone on ultrasonography. Prenatal diagnosis with high sensitivity and specificity can be achieved by assaying fetal DNA that is circulating in maternal blood. *The chance of bearing a child with Down syndrome increases exponentially with the age of the mother at conception and begins a marked rise after age 35 years.* By age 45 years, the odds of having an affected child are as high as 1 in 40. The risk of other conditions associated with trisomy also increases, because of the predisposition of older oocytes to nondisjunction during meiosis. The risk of trisomy 21 is not increased in older fathers.

Clinical Findings

A. Symptoms and Signs

Down syndrome is usually diagnosed at birth on the basis of the typical craniofacial features, hypotonia, and single palmar crease. Several serious problems that may be evident at birth or may develop early in childhood include duodenal atresia, congenital heart disease (especially atrioventricular canal defects), and hematologic malignancy. The intestinal and cardiac anomalies usually are correctible by surgery. A transient neonatal leukemia generally responds to conservative management. The incidences of both acute lymphoblastic and especially myeloid leukemias are increased in childhood. Leukemia typically responds to reduced-dose chemotherapy, but if relapse occurs, outcome is poor. Intelligence varies across a wide spectrum. Other frequent complications include atlanto-axial instability, immune deficiency that predisposes to celiac disease, diabetes mellitus, frequent infections, and hypothyroidism. Many people with Down syndrome do well in sheltered workshops and group homes, but few achieve full independence in adulthood. An Alzheimer-like dementia usually becomes evident in the fourth or fifth decade of life. Patients with Down syndrome who survive childhood and who develop dementia have a reduced life expectancy; on average, they live to about age 55 years.

B. Laboratory Findings

Cytogenomic analysis should always be performed—even though most patients will have simple trisomy for chromosome 21—to detect unbalanced translocations; such patients may have a parent with a balanced translocation, and there will be a substantial recurrence risk of Down syndrome in future offspring of that parent and potentially that parent's relatives.

Treatment

Duodenal atresia should be treated surgically. Congenital heart disease should be treated as in any other patient. As yet, no medical treatment has been proven to affect the neurodevelopmental or the neurodegenerative aspects. Trials of supplementation with antioxidants have shown no benefit.

When to Refer

- For comprehensive evaluation of infants to investigate congenital heart disease, hematologic malignancy, and duodenal atresia.
- For genetic counseling of the parents.
- For signs of dementia in an adult patient.

When to Admit

A young patient should be hospitalized for failure to thrive, regurgitation, or breathlessness.

FAMILIAL HYPERCHOLESTEROLEMIA

ESSENTIALS OF DIAGNOSIS

- Elevated serum total cholesterol and LDL cholesterol.
- Autosomal dominant inheritance.
- Variation in *LDLR*, *PCSK9*, or *APOB*.

General Considerations

Familial hypercholesterolemia (FH) is a group of autosomal dominant and recessive conditions that result in elevated LDL levels in the blood. High LDL predisposes to atherosclerosis, which in turn leads to premature MI and stroke. The incidence of these serious complications increases with age and when associated with the other common predispositions to atherosclerosis, such as smoking and hypertension. About 1 in 500 people in the United States has FH; worldwide, the prevalence is about 10 million. Only about 15% of FH cases are diagnosed and even fewer are treated effectively. Individuals who inherit two copies of a mutant gene that causes FH have a more severe disease that typically presents in childhood with severe hypercholesterolemia and early-onset arterial disease.

Clinical Findings

A. Symptoms and Signs

Yellow lipid deposits appear on tendons, especially the Achilles (**tendon xanthoma**).

B. Laboratory Findings

Total serum cholesterol with the LDL component is particularly high. A detailed family history and genetic testing should be obtained when individuals are younger than 40 years with an LDL level > 200 mg/mL and for individuals older than 40 years with a level > 250 mg/mL.

Prevention

In most instances, the elevated LDL is inherited as an autosomal dominant trait. An affected individual in all likelihood inherited FH from one parent, and each of his or her children has a 50/50 chance of inheriting FH. In uncommon cases, both parents have a variation in the LDL receptor and one-quarter of their children, on average, will inherit two pathogenic variant alleles and have homozygous FH, which is a much more serious disease with manifestations in childhood.

Pathogenic variations in the following four genes can cause FH: (1) *LDLR*, which encodes the LDL receptor located on the surface of cells and responsible for moving LDL into the cell for metabolism is the most common variant gene in FH; (2) *APOB*, which encodes a component of LDL and pathogenic variants inhibit binding to LDL receptor; (3) *PCSK9*, which encodes a protein that normally reduces production of LDL receptors, so variants actually protect from hypercholesterolemia; and (4) *ARH*, a rare cause of FH that requires pathogenic variants in both alleles (autosomal recessive inheritance).

Treatment

Statins, usually at high doses, can reduce LDL levels, occasionally to acceptable levels (see Table 33–3). The earlier in life that treatment is begun, the better the outcome in reducing mortality from atherosclerosis. In homozygous FH, if high-dose statins do not reduce LDL sufficiently, treatment with a monoclonal antibody (eg, alirocumab and evolocumab) that blocks the action of the *PCSK9* enzyme (which inactivates hepatic receptors that transport LDL into the liver for metabolism) can be an expensive adjunct to standard therapy (see Chapter 33). If all else fails, then apheresis is needed to reduce LDL.

It is important to screen relatives who are at risk for FH by measuring LDL levels and by identifying the pathogenic genetic variant in the family and utilizing that for screening.

When to Refer

- For comprehensive evaluation of infants for their lipid profile.
- For genetic counseling of the patient, his or her parents, siblings, and offspring.
- For signs of atherosclerotic CVD.

When to Admit

For signs or symptoms of acute arterial occlusive events.

FRAGILE X SYNDROME

ESSENTIALS OF DIAGNOSIS

- Expanded trinucleotide repeat (> 200) in the *FMR1* gene.
- Males: mental impairment and autism; large testes after puberty.
- Females: learning disabilities or mental impairment; premature ovarian failure.
- Late-onset tremor and ataxia in males and females with moderate trinucleotide repeat (55–200) expansion (premutation carriers).

Clinical Findings

A. Symptoms and Signs

This X-linked condition accounts for more cases of mental impairment in males than any condition except Down syndrome; about 1 in 4000 males is affected. The CNS phenotype includes autism spectrum, impulsivity and aggressiveness, and repetitive behaviors. The condition also affects intellectual function in females, although less severely and about 50% less frequently than in males. Affected (heterozygous) young women show no physical signs other than early menopause, but they may have learning difficulties, anxiety, sensory issues, or frank impairment. Affected males show macroorchidism (enlarged testes) after puberty, large ears and a prominent jaw, a high-pitched voice, autistic characteristics, and mental impairment. Some males show evidence of a mild connective tissue defect, with joint hypermobility and mitral valve prolapse.

Women who are premutation carriers (55–200 CGG repeats) are at increased risk for **premature ovarian insufficiency (FXPOI)** and mild cognitive abnormalities. Male and female premutation carriers are at risk for mood and anxiety disorders and the development of tremor and ataxia beyond middle age (**fragile X-associated tremor/ataxia syndrome, FXTAS**). Changes in the cerebellar white matter may be evident on MRI before symptoms appear. Because of the relatively high prevalence of premutation carriers in the general population (1/130–1/600), older people in whom any of these behavioral or neurologic problems develop should undergo testing of the *FMR1* locus.

B. Laboratory Findings

The first marker for this condition was a small gap, or fragile site, evident near the tip of the long arm of the X chromosome. Subsequently, the condition was found to be due to expansion of a trinucleotide repeat (CGG) near a gene called *FMR1*. All individuals have some CGG repeats in this location, but as the number increases beyond 52, the chances of further expansion during spermatogenesis or oogenesis increase.

Being born with one *FMR1* allele with 200 or more repeats results in mental impairment in most men and in about 60% of women. The more repeats, the greater the likelihood that further expansion will occur during gametogenesis; this results in anticipation, in which the disorder can worsen from one generation to the next.

Prevention

DNA diagnosis for the number of repeats has supplanted cytogenetic analysis for both clinical and prenatal diagnosis. This should be done on any male or female who has unexplained mental impairment. Newborn screening based on hypermethylation of the *FMR1* gene is being considered as a means of early detection and intervention.

Treatment

No treatment directly addresses the underlying genetic perturbation. Several treatments (lovastatin plus minocycline) that address the imbalances in neurotransmission have been developed based on the mouse model and show promise in early clinical trials. Valproic acid may reduce symptoms of hyperactivity and attention deficit, but standard therapies should be tried first.

When to Refer

- For otherwise unexplained mental impairment or learning difficulties in boys and girls.
- For otherwise unexplained tremor or ataxia in middle-aged individuals.
- For premature ovarian failure.
- For genetic counseling.

GAUCHER DISEASE

ESSENTIALS OF DIAGNOSIS

- Deficiency of β-glucocerebrosidase.
- Anemia and thrombocytopenia.
- Hepatosplenomegaly.
- Pathologic fractures.

Clinical Findings

A. Symptoms and Signs

Gaucher disease has an autosomal recessive pattern of inheritance. A deficiency of β-glucocerebrosidase causes an accumulation of sphingolipid within phagocytic cells throughout the body. Anemia and thrombocytopenia are common and may be symptomatic; both are due primarily to hypersplenism, but marrow infiltration with Gaucher cells may be a contributing factor. The abdomen can become painfully distended due to enlargement of the liver and spleen. Soft tissue masses, **Gaucheromas**, can occur anywhere in the body.

Cortical erosions of bones, especially the vertebrae and femur, are due to local infarctions, but the mechanism is unclear. Episodes of bone pain (termed "crises") are reminiscent of those in sickle cell disease. *A hip fracture in a patient of any age with a palpable spleen—especially in a Jewish person of Eastern European origin—suggests the possibility of Gaucher disease.* Peripheral neuropathy may develop in patients.

Patients with Gaucher disease and heterozygous carriers of a pathogenic variant in *GBA* are at increased risk for early-onset Parkinson disease and dementia with Lewy bodies.

Two uncommon forms of Gaucher disease, called **type II** and **type III**, involve neurologic accumulation of sphingolipid and a variety of neurologic problems. Type II is of infantile onset and has a poor prognosis. Heterozygotes for Gaucher disease are at increased risk for developing Parkinson disease.

B. Laboratory Findings

Bone marrow aspirates reveal typical Gaucher cells, which have an eccentric nucleus and periodic acid–Schiff (PAS)-positive inclusions, along with wrinkled cytoplasm and inclusion bodies of a fibrillar type. In addition, the serum acid phosphatase is elevated. Definitive diagnosis requires the demonstration of deficient glucocerebrosidase activity in leukocytes. Hundreds of pathogenic variants cause Gaucher disease and some are highly predictive of the neuronopathic forms. Thus, genetic testing, especially in a young person, is of potential value. Only four pathogenic variants in glucocerebrosidase account for > 90% of the disease among Ashkenazi Jews, in whom the carrier frequency is 1:15.

Prevention

Gaucher disease is the most common lysosomal storage disorder. *Most clinical complications can be prevented by early institution of enzyme replacement therapy.* Carrier screening, especially among those of Ashkenazi Jewish descent, detects those couples at 25% risk of having an affected child. Prenatal diagnosis through genetic variant analysis is feasible. Because of an increased risk of malignancy, especially plasma cell myeloma and other hematologic cancers, regular screening of adults with Gaucher disease is warranted.

Treatment

Several recombinant forms of the enzyme glucocerebrosidase for intravenous administration on a regular basis reduces total body stores of glycolipid and improves orthopedic and hematologic manifestations. *Unfortunately, the neurologic manifestations of types II and III have not improved with enzyme replacement therapy.* The major drawback is the exceptional cost of enzyme replacement therapy. Eliglustat tartrate is an oral inhibitor of glucosylceramide synthase and reduces the compound that accumulates; while still quite expensive, this approach eliminates the need for frequent intravenous infusions. Early treatment of affected children normalizes growth and bone mineral density and improves liver and spleen size, anemia, and thrombocytopenia. In adults with thrombocytopenia due to splenic sequestration, enzyme replacement often obviates the need for splenectomy.

DISORDERS OF HOMOCYSTEINE METABOLISM

ESSENTIALS OF DIAGNOSIS

- Hyperhomocysteinemia: more vascular disease but lowering homocysteine levels is not helpful.
- Homocystinuria: Marfan-like habitus, ectopia lentis, mental impairment, thromboses.
- Elevated homocysteine in the urine or plasma.

General Considerations

Patients with clinical and angiographic evidence of CAD and cerebrovascular and peripheral vascular diseases and VTE tend to have higher levels of plasma homocysteine than persons without these vascular diseases. Elevated blood homocysteine also increases the risk of Alzheimer dementia in the older adults. Although these effects were initially thought to be due at least in part to heterozygotes for cystathionine β-synthase deficiency, there is little supporting evidence. Rather, an important factor leading to hyperhomocysteinemia is folate deficiency. Pyridoxine (vitamin B_6) and vitamin B_{12} are also important in the metabolism of methionine, and deficiency of any of these vitamins can lead to accumulation of homocysteine. *Several genes influence utilization of these vitamins and can predispose to deficiency.* For example, having one copy—and especially two copies—of an allele that causes thermolability of methylene tetrahydrofolate reductase predisposes people to elevated fasting homocysteine levels. Both nutritional and most genetic deficiencies of these vitamins can be corrected by dietary supplementation of folic acid and, if serum levels are low, vitamins B_6 and B_{12}. In the United States, cereal grains are fortified with folic acid. However, therapy with B vitamins and folate lowers homocysteine levels significantly but does not reduce the risk of either VTE or complications of CAD. Hyperhomocysteinemia occurs with ESKD. In the general population, elevated homocysteine correlates with cognitive impairment.

Clinical Findings

A. Symptoms and Signs

1. Hyperhomocysteinemia—Debate continues as to whether mild elevation of plasma homocysteine predisposes to occlusive arterial disease. Adults with hyperhomocysteinemia and associated vitamin deficiencies such as folate, pyridoxine, or vitamin B_{12} may have symptoms of the associated vitamin deficiencies.

2. Homocystinuria—In its classic form, homocystinuria is caused by cystathionine β-synthase deficiency and exhibits autosomal recessive inheritance with a prevalence of 1 per 100,000. This results in extreme elevations of plasma and urinary homocysteine levels, a basis for diagnosis of this disorder. Homocystinuria is similar in certain superficial aspects to Marfan syndrome, since patients may have a similar body habitus and ectopia lentis is almost always present. However, mental impairment is often present in homocystinuria, and the cardiovascular events are those of repeated venous and arterial thromboses whose precise cause remains obscure. Thus, the diagnosis should be suspected in patients in the second and third decades of life who have arterial or venous thromboses without other risk factors. Bone mineral density is reduced in untreated patients. Life expectancy is reduced, especially in untreated and pyridoxine-unresponsive patients; MI, stroke, and PE are the most common causes of death. This condition is diagnosed by newborn screening for hypermethioninemia; however, pyridoxine-responsive infants may not be detected. In addition, homozygotes for a common pathogenic allele, p.I278T, show marked clinical variability, with some unaffected as adults.

B. Laboratory Findings

Although many variations have been identified in the cystathionine β-synthase (*CBS*) gene, amino acid analysis of plasma remains the most appropriate diagnostic test. Patients should be studied after they have been off folate or pyridoxine supplementation for at least 1 week. Relatively few laboratories provide highly reliable assays for homocysteine. Processing of the specimen is crucial to obtain accurate results. The plasma must be separated within 30 minutes; otherwise, blood cells release the amino acid and the measurement will then be artificially elevated.

Prevention

Prenatal diagnosis and termination of the affected pregnancy are the only way to prevent the occurrence of *CBS*-deficient homocystinuria. Clinicians need to be aware of laws regarding the availability of emergency contraception and abortion in the jurisdiction of their practice.

Treatment

About 50% of patients have a form of *CBS* deficiency that improves biochemically and clinically through pharmacologic doses of pyridoxine (50–500 mg orally daily) and folate (5–10 mg orally daily). For these patients, treatment that begins in infancy can prevent neurologic impairment and the other clinical problems. Patients who do not respond to pyridoxine must be treated with a dietary reduction in methionine and supplementation of cysteine, again beginning in infancy. The vitamin betaine is also useful in reducing plasma methionine levels by facilitating a metabolic pathway that bypasses the defective enzyme.

Patients with classic homocystinuria who have suffered venous thrombosis receive anticoagulation therapy, but there are no studies to support prophylactic use of warfarin or antiplatelet agents.

TURNER SYNDROME (Gonadal Dysgenesis)

ESSENTIALS OF DIAGNOSIS

- Short stature with normal GH levels.
- Primary amenorrhea or early ovarian failure.
- Epicanthal folds, webbed neck, short fourth metacarpals.
- Renal and cardiovascular anomalies.

Turner syndrome comprises a group of X chromosome disorders that are associated with spontaneous abortion, primary hypogonadism, short stature, and other phenotypic anomalies (Table 45–2). It affects 1–2% of fetuses, of which about 97% abort, accounting for about 10% of all spontaneous abortions. Nevertheless, it affects about 1 in every 2500 live female births. Patients with the classic syndrome (about 50% of cases) lack one of the two X chromosomes (45,XO karyotype). About 12% of patients harbor mosaicism for Y chromosome sequences. Other patients with Turner syndrome have X chromosome abnormalities, such as ring X or Xq (X/abnormal X) or X chromosome deletions affecting all or some somatic cells (mosaicism, XX/XO).

1. Classic Turner Syndrome (45,XO Gonadal Dysgenesis)

Clinical Findings

A. Symptoms and Signs

Features of Turner syndrome are variable and may be subtle in girls with mosaicism. Turner syndrome may be diagnosed in infant girls at birth, since they tend to be small and may exhibit severe lymphedema. Evaluation for childhood short stature often leads to the diagnosis. Girls and women with Turner syndrome have an increased risk of aortic coarctation and bicuspid aortic valves; these cardiac abnormalities are more common in patients with a webbed neck. Typical manifestations in adulthood include short stature, hypogonadism, webbed neck, high-arched palate, wide-spaced nipples, hypertension, and kidney abnormalities (Table 45–2). Emotional disorders are common. Affected women are also more prone to autoimmune disease, particularly thyroiditis, IBD, and celiac disease.

Hypogonadism presents as “delayed adolescence” (primary amenorrhea, 80%) or early ovarian failure (20%); girls with 45,XO Turner syndrome who enter puberty are typically found to have mosaicism if other tissues are karyotyped.

B. Laboratory Findings

Hypogonadism is confirmed in girls who have high serum levels of FSH and LH. GH and IGF-1 levels are normal. Karyotyping must employ at least 30 metaphase spreads to detect low-level mosaicism. *The classic monosomy X karyotype represents under 50% of cases.* Since X chromosomes are lost during normal aging, women over age 50 must have over 5% X mosaicism to qualify for the diagnosis of Turner mosaicism.

C. Imaging

A transthoracic ultrasound and MRI scan of the chest and abdomen should be done in all patients with Turner syndrome to determine whether cardiac, aortic, and renal abnormalities are present.

Treatment

For short stature, GH therapy should be started early, ideally by age 4–6 and before age 12 years. GH is given subcutaneously in doses of 50 mcg/kg/day or 4.5 IU/m^2/day; the GH dose is titrated to keep the serum IGF-I levels within 3 SD above the mean for age. Rarely, GH treatment causes pseudotumor cerebri. The oral androgen oxandrolone (0.03–0.05 mg/kg/day) is added after age 10 for girls whose growth is inadequate with GH therapy alone. After age 12 years, estrogen therapy is begun with low doses of transdermal estradiol, with a gradual increase in dose over 2–3 years. Progesterone is added after 2 years of estrogen therapy or if menstrual bleeding occurs.

Complications & Surveillance

Women with Turner syndrome have a reduced life expectancy due in part to their increased risk of diabetes mellitus

Table 45–2. Manifestations of Turner syndrome.

Affected Systems	Symptom, Sign, or Condition
Head and neck features	High-arched palate (35%) Low posterior hairline (40%) Micrognathia (60%) Pterygium colli (webbed neck 40%)
Eye abnormalities	Cataracts, corneal opacities Epicanthal folds (20%) Strabismus (15%) Ptosis (10%)
Ear abnormalities	Conductive hearing loss (30%) and recurrent otitis media (60%) Low-set and posteriorly rotated ears
Cardiovascular anomalies	Aortic dilation or aneurysm (25% with bicuspid aortic valve) Bicuspid aortic valve (30%) with aortic stenosis or regurgitation Coarctation (14%) and cystic medial necrosis of aorta Hypertension (50%, idiopathic or due to coarctation or kidney disease) Partial anomalous pulmonary venous return (18%)
GI disorders	Achlorhydria Celiac disease (8%) Colon carcinoma Hepatic transaminases, elevated (65%) IBD (3%) Primary biliary cholangitis Telangiectasias with bleeding
Kidney abnormalities (60%)	Horseshoe kidney (10%), duplication or abnormal positioning of renal pelvis or ureters (15%)
Gonadal abnormalities	Gonadal dysgenesis (primary amenorrhea 80%) or early ovarian failure (20%)
Skeletal and extremity abnormalities	Short stature (98%) Broad (shield) chest (30%) with wide-spaced hypoplastic nipples Cubitus valgus of arms (50%) and knock knees (35%) Lymphedema of hands and feet (30%) Madelung wrist deformity (5%) Osteopenia (65%) Scoliosis (10%) Short fourth metacarpals (40%)
CNS disorders	Emotional immaturity (40%) Learning disabilities and ADHD (40%) Sensorineural hearing loss
Skin and nail disorders	Hyperconvex nails Keloid formation Pigmented nevi
Associated conditions	Autoimmune (Hashimoto) thyroiditis (37%) Diabetes mellitus (10%) or glucose intolerance (35%) Hyperlipidemia Hyperuricemia Neuroblastoma (1%) Obesity Rheumatoid arthritis

ADHD, attention-deficit/hyperactivity disorder.

(types 1 and 2), hypertension, dyslipidemia, and osteoporosis. Annual surveillance should include a blood pressure determination and laboratory evaluations that include a serum TSH, liver enzymes, BUN, creatinine, and fasting serum lipids and glucose. Audiology exams are recommended every 1–5 years. Bone mineral densitometries should be measured periodically for women over age 18 years.

Bicuspid aortic valves are common and are associated with an increased risk of infective endocarditis, aortic valvular stenosis or regurgitation, and ascending aortic root dilation and dissection. The risk of aortic dissection is increased more than 100-fold in women with Turner syndrome.

Partial anomalous pulmonary vein connections can lead to left-to-right shunting of blood. Adults with Turner syndrome also have a high incidence of ECG abnormalities, such as long QT syndrome.

Patients with the classic 45,XO karyotype have a high risk of renal structural abnormalities, whereas those with 46,X/abnormal X are more prone to malformations of the urinary collecting system.

2. Turner Syndrome Variants

A. 46,X (Abnormal X) Karyotype

Patients with small distal short arm deletions of the X chromosome (Xp−) that include the *SHOX* gene often have short stature and skeletal abnormalities but have a low risk of ovarian failure.

B. 45,XO/46,XX and 45,XO/46,XY Mosaicism

45,XO/46,XX mosaicism results in a modified form of Turner syndrome. Such girls tend to be taller and may have more gonadal function and fewer other manifestations of Turner syndrome.

Patients may have ambiguous genitalia or male infertility with an otherwise normal phenotype.

KLINEFELTER SYNDROME

ESSENTIALS OF DIAGNOSIS

- Males with hypergonadotropic hypogonadism and small testes.
- 47,XXY karyotype.

Clinical Findings

A. Symptoms and Signs

Boys with an extra X chromosome are normal in appearance before puberty; thereafter, they have disproportionately long legs and arms, sparse body hair, a female escutcheon (pattern of pubic hair), gynecomastia, and small testes. Infertility is due to azoospermia; the seminiferous tubules are hyalinized. The incidence is 1 in 660 newborn male infants, but the diagnosis is often not made until a man is evaluated for inability to conceive. Intellectual disability is somewhat more common than in the general population. Many men with Klinefelter syndrome have language-based learning problems. However, their intelligence usually tests within the broad range of normal. In adulthood, detailed psychometric testing may reveal a deficiency in executive skills. The risk of osteoporosis, breast cancer, DVT, and diabetes mellitus is much higher in men with Klinefelter syndrome than in 46,XY men.

B. Laboratory Findings

Low serum testosterone is common. The karyotype is typically 47,XXY, but other sex chromosome anomalies cause variations of Klinefelter syndrome.

Prevention

Screening for cancer (especially of the breast), DVT, and glucose intolerance is indicated.

Treatment

Treatment with testosterone after puberty is advisable but will not restore fertility. However, men with Klinefelter syndrome have had mature sperm aspirated from their testes and injected into oocytes, resulting in fertilization. After the blastocysts have been implanted into the uterus of a partner, conception has resulted. Men with Klinefelter syndrome, however, have an increased risk for aneuploidy in sperm, and therefore, genomic analysis of a blastocyst should be considered before implantation.

MARFAN SYNDROME

ESSENTIALS OF DIAGNOSIS

- Disproportionately tall stature, thoracic deformity, and joint laxity or contractures.
- Ectopia lentis and myopia.
- Aortic root dilation and dissection; mitral valve prolapse.
- Variation in *FBN1*, the gene encoding fibrillin-1.

General Considerations

Marfan syndrome, a systemic connective tissue disease, has an autosomal dominant pattern of inheritance. It is characterized by abnormalities of the skeletal, ocular, and cardiovascular systems; spontaneous pneumothorax; dural ectasia; and striae atrophicae. Of most concern is disease of the ascending aorta, which begins as a dilated aortic root. Histology of the aorta shows diffuse medial degeneration. Mitral valve prolapse is common and frequently leads to regurgitation.

Clinical Findings

A. Symptoms and Signs

Affected patients are typically tall, with particularly long arms, legs, and digits (**arachnodactyly**). However, there can be wide variability in the clinical presentation. Commonly, scoliosis and anterior chest deformity, such as pectus excavatum, are present. Ectopia lentis is present in about half of patients; severe myopia is common and retinal detachment can occur. Mitral valve prolapse is seen in more than half of patients. Aortic root dilation is common and leads to aortic regurgitation or dissection with rupture. Aneurysms of aortic branch arteries are more common than previously recognized. To diagnose Marfan syndrome, people with an affected relative need features in at least two systems. People with no family history need features in the skeletal system, two other systems, and one of the major criteria of ectopia lentis, dilation of the aortic root or aortic dissection or a pathogenic variant in *FBN1*.

B. Laboratory Findings

Pathogenic variants in the fibrillin gene (*FBN1*) on chromosome 15 cause Marfan syndrome. Nonetheless, no simple laboratory test is available to support the diagnosis in questionable cases because related conditions may also be due to defects in fibrillin. The pathogenesis of Marfan syndrome involves aberrant regulation of transforming growth factor (TGF)-β activity. Pathogenic variants in either of two receptors for TGF-β (TGFBR1 and TGFBR2) can cause conditions that resemble Marfan syndrome in terms of aortic aneurysm and dissection and autosomal dominant inheritance. Variations in more than two dozen other genes can predispose adults to thoracic aortic aneurysm and dissection.

Prevention

There is prenatal and presymptomatic diagnosis for patients in whom the molecular defect in *FBN1* has been found.

Treatment

Children with Marfan syndrome require regular ophthalmologic surveillance to detect ectopia lentis, correct visual acuity and thus prevent amblyopia, and annual orthopedic consultation for diagnosis of scoliosis at an early enough stage so that bracing might delay progression. Patients of all ages require echocardiography at least annually to monitor aortic root diameter and mitral valve function. Long-term β-adrenergic blockade, titrated to individual tolerance but enough to produce a negative inotropic effect (eg, atenolol, 1–2 mg/kg orally daily), retards the rate of aortic dilation. Angiotensin receptor blockade is as effective as β-adrenergic blockade. Calcium channel blockers, once used as a substitute for β-blockade, are detrimental to the aorta. Restriction from vigorous physical exertion protects from aortic dissection; moderate exercise does not. *Prophylactic replacement of the aortic root when the diameter reaches 45–50 mm in an adult (normal: < 40 mm) prolongs life*. Earlier prophylactic surgery should be considered when there is a strong family history of aortic dissection or when the diameter of the aortic root increases > 3–4 mm per year. A valve-sparing procedure resuspends the patient's native aortic valve inside a graft that replaces the aneurysmal sinuses of Valsalva and ascending aorta, thus avoiding the need for lifelong anticoagulation. Women with Marfan syndrome are at heightened risk for aortic dissection in the peripartum and postpartum periods. Having an aortic root dimension > 40 mm should prompt consideration for prophylactic, valve-sparing aortic repair before undertaking a pregnancy.

Prognosis

People with Marfan syndrome who are untreated commonly die in the fourth or fifth decade from aortic dissection or HF secondary to aortic or mitral regurgitation. However, because of earlier diagnosis, lifestyle modifications, β-adrenergic or angiotensin receptor blockade, and prophylactic aortic and mitral valve surgery, life expectancy has increased by several decades. However, with the longer life expectancy, serious comorbidities that were previously infrequent are more common as a result. These comorbidities include obstructive sleep apnea, cardiomyopathy, aneurysms and dissections of the abdominal aorta and peripheral arteries, neurologic problems related to dural ectasia, and degenerative arthritis.

When to Refer

- For detailed ophthalmologic examination.
- For at least annual cardiologic evaluation.
- For moderate or more severe scoliosis.
- For pregnancy in a woman with Marfan syndrome.
- For genetic counseling.

When to Admit

Any patient with Marfan syndrome in whom severe or unusual chest pain develops should be hospitalized to exclude pneumothorax and aortic dissection.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

ESSENTIALS OF DIAGNOSIS

- Recurrent epistaxis.
- Mucocutaneous telangiectases.
- Visceral arteriovenous malformations (especially lung, liver, brain, bowel).

Clinical Findings

A. Symptoms and Signs

Hereditary hemorrhagic telangiectasia (HHT), formerly termed "Osler-Weber-Rendu syndrome," is an autosomal dominant disorder of development of the vasculature. Epistaxis may begin in childhood or later in adolescence. Punctate telangiectases of the lips, tongue, fingers, and skin generally appear in later childhood and adolescence. *Arteriovenous malformations (AVMs) can occur at any age in the brain, lungs, and liver.* Bleeding from the GI tract is due to mucosal vascular malformations and usually is not a problem until mid-adult years or later. Pulmonary AVMs can cause hypoxemia (with peripheral cyanosis, dyspnea, and clubbing) and right-to-left shunting (with embolic stroke or brain abscess). The criteria for diagnosis require presence of three of the following four features: (1) recurrent epistaxis, (2) visceral AVMs, (3) mucocutaneous telangiectases, and (4) being the near relative of a clearly affected individual. Variant analysis can be used for presymptomatic diagnosis or exclusion of the worry of HHT.

B. Laboratory Findings

MR or CT arteriography detects AVMs. Variants in at least five genes can cause HHT. Molecular analysis to identify three of these genes is available; variants in *ENG, ALK1*, and *SMAD4* account for about 87% of families with HHT. When the familial variant is known, molecular testing is far more cost-effective than repeated clinical screening of relatives who are at risk.

Prevention

Embolization of pulmonary AVMs with wire coils or other occlusive devices reduces the risk of stroke and brain abscess. Treatment of brain AVMs reduces the risk of hemorrhagic stroke. All patients with HHT with evidence of a pulmonary shunt should practice routine endocarditis prophylaxis. All intravenous lines (except those for transfusion of RBCs and radiographic contrast) should have an air-filter to prevent embolization of an air bubble. Prenatal diagnosis through variant detection is possible. All patients should be referred for genetic counseling.

Treatment

All patients in whom the diagnosis of HHT is considered should have an MRI of the brain with contrast. A contrast echocardiogram will detect most pulmonary AVMs when "bubbles" appear on the left side of the heart after 3–6 cardiac cycles. A positive contrast echocardiogram should be followed by an HRCT angiogram for localization of pulmonary AVMs. Patients who have AVMs with a feeding artery of 2 mm diameter or greater should undergo embolization. After successful embolization of all treatable pulmonary AVMs, the CT angiogram should be repeated in 6 months and 3 years. A person with a negative contrast echocardiogram should have the test repeated every 5 years. *Any person with a pulmonary AVM, even an embolized one, should utilize routine endocarditis prophylaxis.* Several studies suggest that treatment with anti-estrogenic agents (eg, tamoxifen), thalidomide or its relatives, or anti-vascular endothelial growth factor agents (eg, bevacizumab) can reduce epistaxis and GI bleeding and improve hepatic shunting. However, two randomized, controlled clinical trials of intranasal bevacizumab therapy failed to show an improvement in epistaxis.

Orthopedic Disorders & Sports Medicine

Anthony Luke, MD, MPH
C. Benjamin Ma, MD

Musculoskeletal problems account for about 10–20% of outpatient primary care clinical visits. Orthopedic problems can be classified as atraumatic (ie, degenerative or overuse syndromes) or traumatic (ie, injury-related) as well as acute or chronic. The history and physical examination are sufficient in most cases to establish the working diagnosis; the mechanism of injury is usually the most helpful part of the history in determining the diagnosis.

SHOULDER

1. Subacromial Impingement Syndrome

ESSENTIALS OF DIAGNOSIS

- Shoulder pain with overhead motion.
- Night pain with sleeping on shoulder.
- Numbness and pain radiation below the elbow are usually due to cervical spine disease.

General Considerations

The subacromial impingement syndrome is a collection of diagnoses that cause mechanical inflammation in the subacromial space, often occurring with shoulder flexion and/or internal rotation. Causes of impingement syndrome include muscle strength imbalances, poor scapula control, rotator cuff tears, subacromial bursitis, and bone spurs.

With any shoulder problem, it is important to establish the patient's hand dominance, occupation, and recreational activities because shoulder injuries may present differently depending on the demands placed on the shoulder joint. Baseball pitchers with impingement syndrome may report pain while throwing, while older adults with even full-thickness rotator cuff tears may not report any pain because the demands on the joint are lower.

Clinical Findings

A. Symptoms and Signs

Subacromial impingement syndrome classically presents with one or more of the following: anterior shoulder pain with overhead activities (arm adduction), nocturnal pain with sleeping on the shoulder, or pain on internal rotation (eg, putting on a jacket or bra). Internal impingement, a less common cause of shoulder pain, is characterized by posterior shoulder pain.

On inspection, there may be atrophy in the supraspinatus or infraspinatus fossa. The patient with impingement syndrome can have mild scapula winging or "dyskinesis." The patient often has a rolled-forward shoulder posture or head-forward posture. On palpation, there may be tenderness over the anterolateral shoulder at the edge of the greater tuberosity. The patient may lack full active range of motion but has preserved passive range of motion. Impingement symptoms can be elicited with the Neer and Hawkins impingement signs (Table 46–1). Most examination maneuvers, however, have low diagnostic accuracy and low quality of evidence; therefore the use of several maneuvers is recommended to confirm suspected pathologies.

B. Imaging

Four radiographic views should be ordered to evaluate subacromial impingement syndrome: (1) the anteroposterior (AP) scapula (to rule out glenohumeral joint arthritis); (2) the AP acromioclavicular joint (to evaluate the acromioclavicular joint for inferior spurs); (3) the lateral scapula (scapular Y) (to evaluate the acromial shape); and (4) the axillary lateral (to visualize the glenohumeral joint and show the presence of os acromiale). The presence of a subacromial spur does not correlate with shoulder function.

MRI of the shoulder may demonstrate full- or partial-thickness tears or tendinosis. Ultrasound evaluation may demonstrate thickening of the rotator cuff tendons and tendinosis. Tears may also be visualized, and while it is

Table 46–1. Shoulder examination.

Maneuver	Description
Inspection	Check patient's posture and for "SEADS" (*s*welling, *e*rythema, *a*trophy, *d*eformity, *s*urgical scars).
Palpation	Include important landmarks: acromioclavicular (AC) joint, long head of biceps tendon, coracoid, and greater tuberosity (supraspinatus insertion).
Range of motion testing: Check range of motion actively (patient performs) and passively (clinician performs).	
Flexion  	Move the arm forward as high as possible in the sagittal plane.
External rotation  	Check with the patient's elbow touching their body so that external rotation occurs predominantly at the glenohumeral joint.

(*continued*)

Table 46–1. Shoulder examination. (continued)

Maneuver	Description
Internal rotation  	Patient reaches the thumbs as high as possible behind the spine on each side. The clinician records the highest spinous process that the individual can reach on each side (iliac crest = L4, inferior angle of scapula = T8).
Rotator Cuff Strength Testing	
Supraspinatus (open can) test 	Perform resisted shoulder abduction at 90 degrees with slight forward flexion to around 45 degrees to test for supraspinatus tendon strength (“open can” test), or with shoulder abduction at 30 degrees and flexion to 30 degrees (“empty can” test).
External rotation 	The patient resists by externally rotating the arms with elbows at their side.

(*continued*)

Table 46–1. Shoulder examination. (continued)

Maneuver	Description
Internal rotation (lift-off test) 	The clinician pushes the patient's hand toward the back while the patient resists. A positive lift-off indicates subscapularis tendon insufficiency. **Positive test:** Inability of the patient to hold their or her hand away from the body when reaching toward the small of the back.
Internal rotation (belly-press test) 	With the patient standing, the clinician puts the patient's forearm on the abdomen with the elbow flexed and the arm maximally internally rotated. The clinician places their hand between the patient's hand and abdomen to assess the patient's strength as the patient presses the arm against the abdomen with the elbow remaining forwardly flexed. A positive belly-press test indicates subscapularis tendon insufficiency. **Positive test:** Inability to hold the elbow in front of the trunk while pressing down with the hand on the abdomen.
Impingement Testing	
Neer impingement sign 	Perform by having the clinician flex the shoulder maximally in an overhead position. **Positive test:** Pain is reproduced with full passive shoulder flexion. Sensitivity is 79%; specificity is 53%.

(*continued*)

Table 46–1. Shoulder examination. (continued)

Maneuver	Description
Hawkins impingement sign 	Perform with the shoulder forward flexed 90 degrees and the elbow flexed at 90 degrees. The shoulder is then maximally internally rotated to impinge the greater tuberosity on the undersurface of the acromion. **Positive test:** Pain is reproduced by this maneuver. Sensitivity is 79%; specificity is 59%.
Stability Testing	
Apprehension test 	With persistent anterior instability or a recent dislocation, the patient feels pain or guards when the shoulder is abducted and externally rotated at 90 degrees. With posterior instability, the patient is apprehensive with the shoulder forward flexed and internally rotated to 90 degrees with a posteriorly directed force.
Load and shift test 	Perform to determine shoulder instability by manually moving the humeral head anteriorly and posteriorly in relation to the glenoid. However, this test can be difficult to perform when the patient is not relaxed.
O'Brien test  	Performed to rule out labral cartilage tears that often occur following a shoulder subluxation or dislocation. The test involves flexing the patient's arm to 90 degrees, fully internally rotating the arm so the thumb is facing down (palm down), and adducting the arm to 10 degrees. Once positioned properly, the clinician applies downward force and asks the patient to resist. The test is then repeated in the same position except that the patient has his arm fully supinated (palm up). **Positive test:** There is pain deep in the shoulder with palm down more than the palm up. The O'Brien test can also be used to identify AC joint pathology. The patient would typically report pain equally directly over the AC joint with the palm down or up.

more difficult to identify partial tears from small full-thickness tears on ultrasound than on MRI, the technique has improved significantly. Ultrasound can also help in the evaluation of patients with previous hardware in the shoulder, making an MRI difficult to interpret, or for the early postoperative healing phase when the tendon has not healed completely.

Treatment

A. Conservative

The first-line treatment for impingement syndrome is usually a conservative approach with education, activity modification, and physical therapy exercises.

Impingement syndrome can be caused by muscle weakness or tear. Rotator cuff muscle strengthening can alleviate weakness or pain, unless the tendons are seriously compromised, in which case exercises may cause more symptoms. Physical therapy is directed at rotator cuff muscle strengthening, scapula stabilization, and postural exercises. There is no strong evidence supporting the effectiveness of ice and NSAIDs as prolonged therapy. In a Cochrane review, corticosteroid injections produced slightly better relief of symptoms in the short term when compared with placebo. Most patients respond well to conservative treatment.

B. Surgical

Procedures include arthroscopic acromioplasty with coracoacromial ligament release, bursectomy, or debridement or repair of rotator cuff tears. However, the value of acromioplasty alone for rotator cuff problems is not supported by evidence.

When to Refer

- Failure of conservative treatment over 3 months.
- Young and active patients with impingement due to full-thickness rotator cuff tears.

Liaghat B et al. Diagnosis, prevention and treatment of common shoulder injuries in sport: grading the evidence - a statement paper commissioned by the Danish Society of Sports Physical Therapy (DSSF). Br J Sports Med. 2023;57:408. [PMID: 36261251]

2. Rotator Cuff Tears

ESSENTIALS OF DIAGNOSIS

- A common cause of shoulder impingement syndrome after age 40 years.
- Difficulty lifting the arm with limited active range of motion.
- Weakness with resisted strength testing suggests full-thickness tears.
- Tears can occur following trauma or can be more degenerative.

General Considerations

Rotator cuff tears can be caused by acute injuries related to falls on an outstretched arm or to pulling on the shoulder. They may also develop from recurrent tendon strain from repetitive lifting or impingement from overhead movement. Partial rotator cuff tears often occur first. Full-thickness rotator cuff tears are usually more symptomatic and may require surgical treatment. The most commonly torn tendon of the shoulder is the supraspinatus.

Clinical Findings

A. Symptoms and Signs

Most patients report weakness, pain with overhead movement, or night pain. The clinical findings with rotator cuff tears include those of the impingement syndrome—but with full-thickness rotator cuff tears there may be more obvious weakness noted with light resistance testing of specific rotator cuff muscles. Table 46–1 demonstrates tests for supraspinatus tendon strength test (“open can” test), infraspinatus/teres minor strength and subscapularis strength, and the Neer and Hawkins impingement tests.

B. Imaging

Recommended radiographs are similar to impingement syndrome: AP scapula (glenohumeral), AP acromioclavicular joint views, lateral scapula (scapula Y), and axillary lateral. The AP scapula view is useful to visualize rotator cuff tears because degenerative changes can appear between the acromion and greater tuberosity of the shoulder, and to assess for arthritic changes. The elevation of the humeral head in relation to the glenoid also indicates large or “massive” rotator cuff tears. The AP acromioclavicular joint view evaluates for the presence of acromioclavicular joint arthritis, which can mimic rotator cuff tears, and for spurs that can cause rotator cuff impingement. Supraspinatus outlet views allow evaluation of the shape of the acromion. Axillary lateral views show the relationship of the humerus on the glenoid and can detect instability or dislocations. MRI is the best method for visualizing rotator cuff tears. The MR arthrogram can show partial or small (< 1 cm) rotator cuff tears. For patients who cannot undergo MRI testing or when postoperative artifacts limit MRI evaluations, ultrasonography can be helpful.

Treatment

1. Partial rotator cuff tears—Most partial rotator cuff tears can be treated conservatively with physical therapy and scapular and rotator cuff muscle strengthening. However, about 40% of the partial-thickness tears progress to full-thickness tears in 2 years. Physical therapy can strengthen the remaining muscles to compensate for loss of strength and can have high rate of success for chronic tears. Physical therapy is also an option for older sedentary patients. Injection of corticosteroids or platelet-rich plasma (PRP) may provide symptomatic relief.

2. Full-thickness rotator cuff tears—These tears do not heal well and have a tendency to increase in size with time; 49% of the tears get bigger over an average of 2.8 years. Evidence suggests that physical therapy is indicated initially for atraumatic degenerative rotator cuff tears, with success rates up to 70%. Ten-year studies, however, show that surgical repair of rotator cuff tears can result in better outcomes than physical therapy alone. When tears get larger, they are associated with worsening pain. Factors for good surgical outcome include patient age < 65 years, smaller tears with little retraction, a remaining tendon stump of 15 mm, early intervention for traumatic tears, and little or no fatty infiltration. Fatty infiltration is an irreversible degenerative process where muscle is replaced by fat following rotator cuff tear. Operative interventions are usually performed when the degree of infiltration is low. Most young active patients with acute, full-thickness rotator cuff tears can consult a shoulder specialist to optimize treatment. Full-thickness subscapularis tendon tears should be evaluated for early surgical repair since untreated tears can lead to premature osteoarthritis (OA) of the shoulder. Corticosteroid injections should be minimized, especially if surgery is a consideration, since injection within 6 months of surgery is associated with a higher surgical revision rate after 3 years.

3. Massive rotator cuff tears—These tears measure ≥ 5 cm. Data are limited, including poor evidence about the timing of surgical repair in order to optimize functional outcomes and reduce pain. For traumatic massive tears, the best practice recommendation is surgical repair within 12 weeks of injury.

When to Refer

- Young and active patients with full-thickness rotator cuff tears.
- Partial tears with 50% or more involvement and with significant pain.
- Acute rotator cuff tears, especially if massive (≥ 5 cm) with retraction.
- Older and sedentary patients with full-thickness rotator cuff tears who have not responded to nonoperative treatment.
- Full-thickness subscapularis tears.

Kuhn JE et al; Multicenter Orthopaedic Outcomes Network (MOON) Shoulder Group. 2024 Kappa Delta Ann Doner Vaughan Award: nonsurgical treatment of symptomatic, atraumatic full-thickness rotator cuff tears-a prospective multicenter cohort study with 10-year follow-up. J Am Acad Orthop Surg. 2024;32:1061. [PMID: 39325825]

3. Shoulder Dislocation & Instability

ESSENTIALS OF DIAGNOSIS

- Most dislocations (95%) are in the anterior direction.
- Pain and apprehension with an unstable shoulder that is abducted and externally rotated.
- Acute shoulder dislocations should be reduced as quickly as possible, using manual relocation techniques if necessary.

General Considerations

Stabilizing the shoulder joint relies heavily on rotator cuff muscle strength and also scapular control. In cases with poor scapular control or rotator cuff tears, shoulders may have more instability. Ninety-five percent of shoulder dislocations/instability occur in the anterior direction. Anterior dislocations usually are caused by stress on the arm in abduction, like a fall on an outstretched arm. Posterior dislocations are usually caused by falls from a height, epileptic seizures, or electric shocks. Traumatic shoulder dislocation can lead to ligamentous and bony injuries. The rate of repeated dislocation is directly related to the patient's age: patients aged 21 years or younger have a 70–90% risk of redislocation, whereas patients aged 40 years or older have a much lower rate (20–30%). However, once the patient has a second dislocation, the recurrence rate is extremely high, up to 95%, regardless of age. Other risks include male sex and patients with hyperlaxity. Ninety percent of young active individuals who had traumatic shoulder dislocation have labral injuries. The labrum is the attachment site for the shoulder ligaments. Patients age > 55 years are more likely to have rotator cuff tears or fractures following dislocation. Atraumatic shoulder dislocations are usually caused by intrinsic ligament laxity or repetitive microtrauma leading to joint instability. This is often seen in athletes involved in overhead and throwing sports (eg, in swimmers, gymnasts, and pitchers).

Clinical Findings

A. Symptoms and Signs

For acute traumatic anterior dislocation, patients have severe pain, with the humeral head dislocated anteriorly causing a deformity, with loss of the normal curve of the shoulder. The patient holds the shoulder and arm in an externally rotated position. Even after reduction, the patient will continue to have limited range of motion and pain for 4–6 weeks, especially following a first-time shoulder dislocation.

Posterior dislocations are harder to detect than anterior dislocations. The patient usually holds the shoulder and arm in an internally rotated position, which makes the shoulder deformity less obvious. There may be severe pain and muscle spasm, but the patient may still be able to move the joint.

Recurrent dislocations often are less painful with subsequent dislocations.

Atraumatic shoulder instability is usually well tolerated with activities of daily living. Patients usually describe a “sliding” sensation or “subluxation” during strenuous activities such as throwing or overhead lifting. Atraumatic dislocations may be less symptomatic and can often undergo spontaneous reduction of the shoulder with pain resolving within days after onset. The clinical examination for shoulder instability includes the apprehension test, the load and shift test, and the O'Brien test (Table 46–1). Most patients with persistent shoulder instability have preserved range of motion.

B. Imaging

Radiographs for acute dislocations should include a standard trauma series of AP and axillary lateral scapula (glenohumeral) views to determine the relationship of the humerus and the glenoid and to rule out fractures. Orthogonal views are used to identify a posterior shoulder dislocation, which can be missed with one AP view of the shoulder. An axillary lateral view of the shoulder can be safely performed even in the acute setting of a painful shoulder dislocation; a scapula Y view in the acute setting is insufficient to diagnose dislocation. For chronic injuries or symptomatic instability, these same recommended radiographic views are helpful to identify bony injuries and Hill-Sachs lesions (indented compression fractures at the posterior-superior part of the humeral head associated with anterior shoulder dislocation causing bone loss). MRI is commonly used to show soft tissue injuries to the labrum and to visualize associated rotator cuff tears. MRI arthrograms better identify labral tears and ligamentous structures. Three-dimensional CT scans are used to determine the significance of bone loss.

Treatment

1. Acute dislocation—Manual reduction is usually performed in the emergency department. The shoulder should be reduced as soon as possible. The FARES (Fast, Reliable, and Safe) method is the least painful method, with success rates > 88.7%. With the patient lying supine, the provider holds the patient's wrist with the arm extended. The provider applies gentle traction to the arm while making small oscillations with the joint in the horizontal plane to slowly abduct the arm to 90 degrees. When the arm reaches 90 degrees, the provider externally rotates the arm to achieve the joint reduction. Another traditional method is the gentle Stimson procedure: the patient lies prone with the dislocated arm hanging off the examination table with a weight (5–10 pounds) applied to the wrist to provide traction for 10–20 minutes. Afterward, gentle medial mobilization of the scapula is applied manually to assist the reduction.

Initial treatment of acute shoulder dislocations should include sling immobilization for 2–4 weeks along with pendulum exercises. Early physical therapy can be used to maintain range of motion and strengthening of rotator cuff muscles. Patients can also modify their activities to avoid active and risky sports. Patients with a traumatic incident and unilateral shoulder dislocation commonly have a Bankart lesion. (The dislocation tears part of the labrum of the glenohumeral joint.) Operative intervention is the only treatment that has been shown to decrease recurrence once a patient has a second dislocation. Repeated dislocations have been shown to increase the risk of arthritis and further bony deterioration. The more significant the bony deterioration, the less successful is the surgical outcome. Open and arthroscopic stabilization have similar outcomes.

2. Atraumatic shoulder instability—The treatment is different than that of traumatic shoulder instability. Patients with chronic, recurrent shoulder dislocations should be managed with physical therapy and a regular maintenance program, consisting of scapular stabilization and postural and rotator cuff strengthening exercises. Activities may need to be modified. Surgical reconstructions are less successful for atraumatic shoulder instability than for traumatic shoulder instability. However, patients with recurrent dislocations have much higher incidence of bone loss or biceps pathology when compared with patients with first-time dislocations. They are also more likely to require open surgery with bone augmentation rather than arthroscopic stabilization.

When to Refer

- Patients who are at risk for second dislocation, such as young patients and those with certain occupations (eg, police officers, firefighters, and rock climbers), to avoid recurrent dislocation or dislocation while at work.
- Patients who have not responded to a conservative approach or who have chronic instability.

Gonai S et al. An umbrella review of systematic reviews and meta-analyses for assessment and treatment of acute shoulder dislocation. Am J Emerg Med. 2025;87:16. [PMID: 39442380]

4. Adhesive Capsulitis ("Frozen Shoulder")

ESSENTIALS OF DIAGNOSIS

- Very painful shoulder triggered by minimal or no trauma.
- Pain out of proportion to clinical findings during the inflammatory phase.
- Stiffness during the "freezing" phase and resolution during the "thawing" phase.

General Considerations

Adhesive capsulitis ("frozen shoulder") is caused by acute inflammation of the shoulder capsule followed by scarring and remodeling. Injury to the shoulder likely triggers mast cell activation and release of growth factors and cytokines. Adhesive capsulitis is seen commonly in patients aged 40–65 years old, and it occurs more often in women than men, especially in perimenopausal women or in patients with endocrine disorders, such as diabetes mellitus or thyroid disease. There is a higher incidence of adhesive capsulitis following shoulder trauma (such as surgery) or breast cancer care (such as mastectomy), which may create a pro-inflammatory condition in the shoulder. Adhesive capsulitis is a self-limiting but very debilitating disease.

Clinical Findings

A. Symptoms and Signs

Patients usually have an extremely painful shoulder that has a limited range of motion with both passive and active movements. A useful clinical sign is limitation of movement of external rotation with the elbow by the side of the trunk (Table 46–1). Strength is usually normal but may appear diminished because of pain.

There are three phases: the inflammatory phase, the freezing phase, and the thawing phase. During the "inflammatory" phase, which usually lasts 4–6 months, patients report a very painful shoulder without obvious clinical findings to suggest trauma, fracture, or rotator cuff tear. During the "freezing" phase, which also usually lasts 4–6 months, the shoulder becomes stiffer and stiffer even though the pain is improving. The "thawing" phase can take up to a year as the shoulder slowly regains its motion. The total duration of an idiopathic frozen shoulder is usually about 24 months; it can be much longer for patients who have trauma or an endocrinopathy.

B. Imaging

Standard AP, axillary, and lateral glenohumeral radiographs are useful to rule out glenohumeral arthritis, which can also present with limited active and passive range of motion. Imaging can also rule out calcific tendinitis, which is an acute inflammatory process in which calcifications are visible in the soft tissue. However, adhesive capsulitis is usually a clinical diagnosis, and it does not need an extensive diagnostic workup.

Treatment

During the "inflammatory" and "freezing" phases, NSAIDs and physical therapy help to maintain motion. There is also evidence of short-term benefit from an intra-articular corticosteroid injection or oral prednisone; a meta-analysis showed that intra-articular corticosteroid injection provided better pain relief than NSAIDs in the first 8 weeks. However, no difference was seen in range of motion or pain after 12 weeks, which is similar to other noncontrolled studies. One study demonstrated improvement at 6 weeks but not 12 weeks following 30 mg of daily prednisone for 3 weeks. During the "freezing" phase, the shoulder is less painful but remains stiff. Anti-inflammatory medication is not as helpful during the "thawing" phase as it is during the "freezing" phase, and the shoulder symptoms usually resolve with time. Intraarticular PRP injections show at least equal benefits to a corticosteroid injection and in one trial showed early gain in range of motion. Surgical treatments, which are rarely indicated, include manipulation under anesthesia and arthroscopic release.

When to Refer

- When the patient does not respond after > 6 months of conservative treatment.
- When there is no progress in or worsening of range of motion over 3 months.

Nudelman B et al. Platelet-rich plasma injections for shoulder adhesive capsulitis are at least equivalent to corticosteroid or saline solution injections: a systematic review of prospective cohort studies. Arthroscopy. 2023;39:1320. [PMID: 36708748]

SPINE PROBLEMS

1. Low Back Pain

ESSENTIALS OF DIAGNOSIS

- Nerve root impingement is suspected when pain is leg-dominant rather than back-dominant.
- Alarm symptoms (red flags) include unexplained weight loss, failure to improve with treatment, severe pain for > 6 weeks, and night or rest pain.
- Cauda equina syndrome is an emergency; it often presents with bowel or bladder symptoms (or both).
- Chronic management should address physical, emotional, cognitive and behavioral dimensions of back pain.

General Considerations

Low back pain remains the number one cause of disability globally and is the second most common cause for primary care visits. The three most attributable risk factors are occupational ergonomic factors, cigarette smoking, and high BMI. Approximately 80% of episodes of low back pain resolve within 2 weeks and 90% resolve within 6 weeks. Chronic low back pain is often defined as back pain for 12 weeks or more. The cause of low back pain is frequently difficult to diagnose; its cause is often multifactorial. The spine develops degenerative changes in the discs, facet joints, and vertebral endplates (Modic changes). Progressive osteoarthritis can narrow the neuroforamen and the spinal canal, resulting in stenosis and further compression of neural structures. The sacroiliac joints, muscles, and tendons also can cause pain.

Clinical Findings

A. Symptoms and Signs

Aggravating factors of flexion and prolonged sitting commonly suggest anterior spine disc problems, while extension pain suggests facet joint, stenosis, or sacroiliac joint problems. Serious causes for back pain include fracture, cancer, infection, cauda equina syndrome, and axial spondyloarthritis (Table 46–2). Red flags are concerning for serious spinal pathology while yellow flags are psychosocial factors in the absence of serious spinal pathology that may increase the likelihood of long-term chronicity and disability (Table 46–3).

1. Vertebral fracture—Risk factors for back pain due to vertebral fracture include use of corticosteroids, age > 70 years, osteoporosis, severe trauma, and presence of a contusion or abrasion.

2. Malignancy—Alarm symptoms for back pain caused by cancer include unexplained weight loss, failure to improve with treatment, pain for > 6 weeks, and pain at night

Table 46–2. Risk factors and symptoms for serious spine pathology.

Fracture
Osteoporosis
Age
Pain worse when lying supine
Early menopause or late menarche
History of fracture
Malignancy
History of cancer
Requiring strong pain medication
Weight loss
Odd sensations in legs
Spinal infection
Immunosuppression
Corticosteroid use
History of tuberculosis
Fever
Neurologic dysfunction
Intravenous drug use
Night pain
Cauda equina syndrome
Bilateral radicular pain
Myotomal weakness
Changes to bladder function
Changes to bowel function
Saddle sensory disturbance
Inflammatory condition
Age
Past enthesitis, psoriasis, or arthritis
Uveitis
IBD
Nerve root condition
Myotomal weakness

Table 46–3. Red and yellow flags for low back pain.[1]

Red Flags		
Patient history	**Medication history**	**Signs and symptoms**
Neoplasms Physical traumas Advanced age > 50 years (cancer risk) > 70 years (fracture risk) Weight loss Immunodeficiency Osteoporosis	Injection drug use Corticosteroid use or other immunosuppressive drug use	High fever (≥ 38°C) Worst pain at night or rest Saddle anesthesia Weakness in lower limbs Bladder or bowel dysfunction (eg, overflow incontinence and urinary detention) Gait disturbance Abrupt, unexplained weight loss Night sweats Inflammatory back pain
Yellow Flags		
High baseline pain and disability Sleep problems Depression Anxiety Pain catastrophizing Work dissatisfaction Poor social support Low socioeconomic status General health-related (eg, opioid use and sedentary lifestyle) Fear-avoidance beliefs Irritability Toxic relationships Reduced perceived control over one's life		

[1] See text for definition of red flags and yellow flags. Derived from Finucane LM et al. International framework for red flags for potential serious spinal pathologies. J Orthop Sports Phys Ther 2020;50:350. [PMID: 32438853]

or rest. History of cancer and age older than 50 years are other risk factors for malignancy.

3. Infection—Alarm symptoms for infection include fever, rest pain, recent infection (UTI, cellulitis, pneumonia), or history of immunocompromise or injection drug use.

4. Cauda equina syndrome—Urinary retention or incontinence, saddle anesthesia, decreased anal sphincter tone or fecal incontinence, bilateral lower extremity weakness, and progressive neurologic deficits are symptoms suggestive of cauda equina syndrome.

5. Other serious causes of back pain—Back pain may also be the presenting symptom in other serious medical problems, including AAA, peptic ulcer disease, kidney stones, or pancreatitis.

Psychosocial factors (yellow flags) and workplace factors should be assessed in cases where acute back pain becomes chronic (Table 46–3). The patient's previous response to treatments and the results of risk prediction tools can help guide management. Most patients with persistent low back pain have co-occurring areas of pain, especially axial pain (18–58%), extremity pain (6–50%), and multisite musculoskeletal pain (10–89%).

B. Physical Examination

The physical examination can be conducted with the patient in the standing, sitting, supine, and finally prone positions to avoid frequent repositioning of the patient.

1. Standing position—The patient's posture can be observed. Commonly encountered spinal asymmetries include scoliosis, thoracic kyphosis, and lumbar hyperlordosis. The active range of motion of the lumbar spine can be assessed while standing. The common directions include flexion, extension, rotation, and lateral bending. The one-leg standing extension test assesses for pain as the patient stands on one leg while extending the spine. A positive test can be caused by pars interarticularis fractures (spondylolysis or spondylolisthesis) or facet joint arthritis.

Table 46–4. Neurologic testing of lumbosacral nerve disorders.

Nerve Root	Motor	Reflex	Sensory Area
L1	Hip flexion	None	Groin
L2	Hip flexion	None	Thigh
L3	Extension of knee	Knee jerk	Knee
L4	Dorsiflexion of ankle	Knee jerk	Medial calf
L5	Dorsiflexion of first toe	Babinski reflex	First dorsal web space between first and second toes
S1	Plantar flexion of foot, knee flexors, or hamstrings	Ankle jerk	Lateral foot
S2	Knee flexors or hamstrings	Knee flexor	Back of the thigh
S2–S4	External anal sphincter	Anal reflex, rectal tone	Perianal area

Table 46–5. AHRQ criteria for lumbar radiographs in patients with acute low back pain even if < 6 weeks in duration.

Possible fracture
- Major trauma
- Minor trauma in patients > 50 years of age
- Long-term corticosteroid use
- Osteoporosis
- > 70 years of age

Possible tumor or infection
- > 50 years of age
- < 20 years of age
- History of cancer
- Constitutional symptoms
- Recent bacterial infection
- Injection drug use
- Immunosuppression
- Supine pain
- Nocturnal pain

AHRQ, Agency for Healthcare Research and Quality.
Adapted from Bigos S et al. Acute Low Back Problems in Adults. Clinical Practice Guideline Quick Reference Guide No. 14. AHCPR Publication No. 95-0643. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services. December 1994.

2. Sitting position—Motor strength, reflexes, and sensation can be tested (Table 46–4). The major muscles in the lower extremities are assessed for weakness by eliciting a resisted isometric contraction for about 5 seconds. Comparing the strength bilaterally to detect subtle muscle weakness is important. Similarly, sensory testing to light touch can be checked in specific dermatomes for corresponding nerve root function. Knee, ankle, and Babinski reflexes can be checked.

3. Supine position—The hip should be evaluated for range of motion, particularly internal rotation. The straight leg raise test puts traction and compression forces on the lower lumbar nerve roots.

4. Prone position—The clinician can carefully palpate each vertebral level of the spine and sacroiliac joints for tenderness. A rectal examination is required if the cauda equina syndrome is suspected. Superficial skin tenderness to a light touch over the lumbar spine, overreaction to maneuvers in the regular back examination, low back pain on axial loading of spine in standing, and inconsistency in the straight leg raise test or on the neurologic examination suggest nonorthopedic causes for the pain or malingering (Waddell signs).

C. Imaging

In the absence of alarming "red flag" symptoms suggesting infection, malignancy, or cauda equina syndrome, most patients do not need diagnostic imaging, including radiographs, in the first 6 weeks. The Agency for Healthcare Research and Quality guidelines for obtaining lumbar radiographs are summarized in Table 46–5. Most clinicians obtain radiographs for new back pain in patients > 50 years of age. If done, radiographs of the lumbar spine should include AP and lateral views. Oblique views can be useful if the neuroforamina or bone lesions need to be visualized. MRI is the method of choice in the evaluation of symptoms not responding to conservative treatment or in the presence of red flags of serious conditions.

D. Special Tests

Electromyography or nerve conduction studies may be useful in assessing patients with possible nerve root symptoms lasting longer than 6 weeks; back pain may or may not also be present. These tests are usually not necessary if the diagnosis of radiculopathy is clear.

▶ Treatment

A. Conservative

Nonpharmacologic treatments are key in the management of low back pain, including education, physical therapy, exercise therapy, and physical activity. Education alone improves patient satisfaction with recovery and recurrence. Patients require information and reassurance, especially when serious pathology is absent. Discussion must include reviewing safe and effective methods of symptom control as well as how to decrease the risk of recurrence with proper lifting techniques, abdominal wall/core strengthening, weight loss, and cigarette smoking cessation. Tobacco may affect the small vessels by reducing the amount of water in the discs and increasing the rate of disc degeneration. Cognitive behavioral therapy and other psychological interventions of even < 10 hours duration produce better outcomes than active physical treatment alone, with post-treatment improvements in pain intensity in the short and long term.

1. Physical therapy—Exercise programs can be tailored to the patient's symptoms and pathology. An RCT demonstrated that individualized physical therapy was clinically more beneficial than advice alone with sustained improvements at 6 months and 12 months. Strengthening and stabilization exercises effectively reduce pain and functional limitation compared with usual care. Heat and cold therapies may be used for symptomatic treatment, with heat therapy showing short-term benefits for acute low back pain. The efficacy of transcutaneous electrical nerve stimulation (TENS), back braces, massage, and physical agents is unproven. There is good evidence that spinal manipulation and acupuncture provide short-term improvement compared with usual care. Improvements in posture, including chair ergonomics or standing desks, core stability strengthening, physical conditioning, and modifications of activities to decrease physical strain, are keys for ongoing management. A multidisciplinary approach to back pain care is beneficial to address the physical, psychological, and social aspects of low back pain, especially when pain is chronic. Opioids should be avoided, if possible.

2. Exercise therapy/physical activity—Systematic reviews of studies of low to moderate quality suggest that various exercises used for pain and disability have short-term benefit with no major difference between types of exercises. Complementary therapies, such as Tai Chi, Pilates, mindfulness-based stress reduction, core strengthening exercises, and yoga, have shown benefit for chronic low back pain. Compared with conventional rehabilitation and no intervention, yoga and core or stabilization exercises were statistically significant in improving physical function in patients with chronic low back pain. There are smartphone and web-based apps and services available to help support and improve self-management of back pain, although the predictive models of these apps are still in the early phase of validation.

3. Pharmacologic treatment—Medications, including oral and topical NSAIDs, and serotonin and norepinephrine reuptake inhibitors (duloxetine), were shown in a systematic review to produce a clinically meaningful reduction in pain. If medications are needed, NSAIDs are effective in the early treatment of low back pain (see Chapter 23 and Table 5–4). Topical capsicum is effective in the short term (≤ 3 months). Acetaminophen and oral corticosteroids are relatively ineffective for non-radicular chronic low back. There is limited evidence that muscle relaxants provide short-term relief; since these medications have addictive potential, they should be used with care. Muscle relaxants are best used if there is true muscle spasm that is painful rather than simply a protective response. Opioids alleviate pain in the short term but have the same side effects and concerns of long-term opioid use (see Chapter 5). Treatment of more chronic neuropathic pain with α2δ ligands (eg, gabapentin), serotonin-norepinephrine reuptake inhibitors (eg, duloxetine), or tricyclic antidepressants (eg, nortriptyline) may be useful (see Table 5–8). Antidepressants are not recommended for the treatment of general low back pain.

B. Nonsurgical Procedures

Procedural interventions include epidural injections of the spine, which may reduce pain in the short term and reduce the need for surgery in some patients within a 1-year period but not longer. Spinal injections are not recommended for initial care of patients with low back pain without radiculopathy. Studies are unclear and of limited quality regarding the effectiveness of PRP injections for low back pain. Intra-articular steroid injections and cooled radiofrequency ablation of the sacral lateral branch nerves and dorsal ramus of L5 can be considered for patients with persistent sacroiliac joint pain. There is fair evidence that thermal radiofrequency ablation of the facet joints improves pain for at least 6 months.

C. Surgical

Indications for back surgery include cauda equina syndrome, ongoing morbidity with minimal response to > 6 months of conservative treatment, cancer, infection, or severe spinal deformity. Prognosis is improved when there is an anatomic lesion that can be corrected and symptoms are neurologic. Spinal surgery has limitations. Patient selection is very important; the specific recommended surgery should have clear indications and expectations. Patients should understand that surgery can improve their pain but is unlikely to cure it. Surgery is not generally indicated for radiographic abnormalities alone when the patient is relatively asymptomatic. Depending on the surgery performed, possible complications include persistent pain; surgical site pain, especially if bone grafting is needed; infection; neurologic damage; non-union; cutaneous nerve damage; implant failure; DVT; and death.

When to Refer

- Patients with cancer, infection, fracture, or severe spinal deformity.
- Patients with severe symptoms affecting quality of life who have not responded to conservative treatment.

When to Admit

Patients with cauda equina syndrome, which requires emergent surgical intervention.

2. Spinal Stenosis

ESSENTIALS OF DIAGNOSIS

- Pain is usually worse with back extension and relieved by sitting.
- Occurs in older patients.
- May present with neurogenic claudication symptoms with walking.

General Considerations

OA in the lumbar spine can cause narrowing of the spinal canal. A large disc herniation can also cause stenosis and compression of neural structures or the spinal artery resulting in "claudication" symptoms with ambulation. The condition usually affects patients aged 50 years or older.

Clinical Findings

Patients report pain that worsens with extension. They describe reproducible single or bilateral leg symptoms that are worse after walking several minutes and that are relieved by sitting ("neurogenic claudication"). On examination, patients often exhibit limited extension of the lumbar spine, which may reproduce the symptoms radiating down the legs. A thorough neurovascular examination is recommended (Table 46–4). MRI and CT of the axial and sagittal lumbar planes enhance detection of lateral recess and central canal stenosis. Increased paraspinal fatty muscle infiltration seen on MRI is associated with increased disability and worse health-related quality of life.

Treatment

A. Conservative

Exercises, usually flexion-based as demonstrated by a physical therapist, can help relieve symptoms. Physical therapy showed similar results as surgical decompression in a randomized trial, though there was a 57% crossover rate from physical therapy to surgery. Facet joint corticosteroid injections can also reduce pain symptoms. While epidural corticosteroid injections have been shown to provide immediate improvements in pain and function for patients with radiculopathy, the benefits are small and only short term. Consequently, there is limited evidence to recommend epidural corticosteroids for spinal stenosis.

B. Surgical

The role of surgery for spinal stenosis is limited. Surgical treatments include spinal decompression (widening the spinal canal or laminectomy), nerve root decompression (freeing a single nerve), and spinal fusion (joining the vertebra to eliminate motion and diminish pain from the arthritic joints). Minimally invasive lumbar decompression does not leave hardware in the spine and patients typically resume unrestricted normal activity within 24 hours. Percutaneous image-guided lumbar decompression uses minimally invasive techniques with instrumentation and image guidance to debulk a thickened ligamentum flavum. In one multicenter randomized trial, subgroups of patients with symptomatic spinal stenosis initially improved significantly more with surgery than with nonoperative treatment. Variables associated with greater treatment effects included better baseline disability scores, not smoking, neuroforaminal stenosis, predominant leg pain rather than back pain, not lifting at work, and the presence of a neurologic deficit. However, long-term follow-up of the patients who received surgery showed less benefit of surgery between 4 and 8 years, suggesting that the advantage of surgery for spinal stenosis diminishes over time. A 2021 meta-analysis comparing fusion and nonfusion surgeries for lumbar spinal stenosis found no difference in clinical effects and complications, highlighting the challenge of surgical intervention for lumbar spinal stenosis. Previous spinal surgery, duration of back pain > 12 months, and age > 70 years were predictors of failure and worsening of symptoms after surgery.

When to Refer

- If a patient exhibits radicular or claudication symptoms for longer than 12 weeks.
- MRI or CT confirmation of significant, symptomatic spinal stenosis.
- However, surgery has not been shown to have clear benefit over nonsurgical treatment for lumbar spinal stenosis.

Alhaug OK et al. Predictors for failure after surgery for lumbar spinal stenosis: a prospective observational study. Spine J. 2023;23:261. [PMID: 36343913]

Deer TR et al. Best Practices for Minimally Invasive Lumbar Spinal Stenosis Treatment 2.0 (MIST): Consensus Guidance from the American Society of Pain and Neuroscience (ASPN). J Pain Res. 2022;15:1325. [PMID: 35546905]

3. Lumbar Disc Herniation

ESSENTIALS OF DIAGNOSIS

- Pain with back flexion or prolonged sitting.
- Radicular pain into the leg due to compression of neural structures.
- Lower extremity numbness and weakness.

General Considerations

Lumbar disc herniation is usually due to bending or heavy loading (eg, lifting) with the back in flexion, causing herniation or extrusion of disc contents (nucleus pulposus) into the spinal cord area. However, there may not be an inciting incident. Disc herniations usually occur from degenerative disc disease (desiccation of the annulus fibrosis) in patients between 30 and 50 years old. The L5–S1 disc is affected in 90% of cases. Compression of neural structures, such as the sciatic nerve, causes radicular pain. Severe compression of the spinal cord can cause the cauda equina syndrome, a surgical emergency.

Clinical Findings

A. Symptoms and Signs

Discogenic pain typically is localized in the low back at the level of the affected disc and is worse with activity. "Sciatica" causes electric shock-like pain radiating down the posterior aspect of the leg often to below the knee. Symptoms usually worsen with back flexion such as bending or sitting for long periods (eg, driving). A significant disc herniation can cause numbness and weakness, including weakness of plantar flexion of the foot (L5/S1) or dorsiflexion of the toes (L4/L5). The cauda equina syndrome should be ruled out if the patient reports perianal numbness or bowel or bladder incontinence.

B. Imaging

Plain radiographs are helpful to assess spinal alignment (scoliosis, lordosis), disc space narrowing, and OA changes. MRI is the best method to assess the level and morphology of the herniation and is recommended if surgery is planned. Provocative lumbar discography (under fluoroscopic guidance, fluid is injected into a disc to pressurize it and a pain response is recorded) can be helpful for identifying the disc as the source of low back pain.

Treatment

For an acute exacerbation of pain symptoms, bed rest is appropriate for up to 48 hours. Otherwise, first-line treatments include modified activities; NSAIDs (Table 5–4) and other analgesics; and physical therapy, including core stabilization and McKenzie back exercises (https://sportsrehab.ucsf.edu/sites/sportsrehab.ucsf.edu/files/Mckenzie%20Back%20Protocol.pdf). The McKenzie exercises identify the mechanical direction of motion in the back that causes more or less pain, using careful history and physical examination to guide the treatment approach. An exercise protocol is designed to centralize or alleviate the pain.

Following nonsurgical treatment for a lumbar disc for > 1 year, the incidence of low back pain recurrence is ≥ 40% and is predicted by longer time to initial resolution of pain. In a randomized trial, oral prednisone caused a modest improvement in function at 3 weeks, but there was no significant improvement in pain in patients with acute radiculopathy who were monitored for 1 year. The initial dose for oral prednisone is approximately 1 mg/kg once daily with tapering doses over 10–15 days. Analgesics for neuropathic pain, such as the α2δ ligands (ie, gabapentin, pregabalin) or tricyclic antidepressants, may be helpful (Table 5–8). Epidural and transforaminal corticosteroid injections can be beneficial. There is moderate-quality evidence that epidural corticosteroid injections are effective, although the treatment effects are small (mean difference < 10%) and short-term for improving radicular pain for individuals. Epidural injections have not impacted long-term surgery rates for disc herniations. There is level I evidence for the use of transforaminal injections for radicular pain from disc herniation. Intradiscal electrothermal therapy has limited success in 40–50% of patients with reduction of pain up to 2 years.

The severity of pain and disability as well as failure of conservative therapy are the most important reasons for surgery. A large trial has shown that patients who underwent surgery for a lumbar disc herniation achieved greater improvement than conservatively treated patients in all primary and secondary outcomes except return-to-work status after 8-year follow-up. Patients with sequestered fragments, symptom duration > 6 months, higher levels of low back pain, or who were neither working nor disabled at baseline showed greater surgical treatment effects. Microdiscectomy is the standard treatment with a low rate of complications and satisfactory results in > 90% in the largest series. It is performed by minimally invasive percutaneous endoscopic spine surgery, where an endoscope is used to remove fragments of disc herniation (interlaminar or transforaminal approaches) under local anesthesia for the treatment of primary and recurrent disc disease. The most commonly reported complications of endoscopic lumbar surgery include dural tear, infection, and epidural hematoma. A systematic review of 14 moderate quality studies suggests that percutaneous endoscopic discectomy and open microdiscectomy have similar results and complications. Patient-related risk factors for recurrent pain after percutaneous endoscopic discectomy include age ≥ 50 years, Modic changes, obesity (BMI ≥ 25), no college education, diabetes, inappropriate manual labor, cigarette smoking, the protrusion type of lumbar disc herniation, and a factor related to the surgical experience of spinal surgeons. Recurrent disc herniations are treated with decompression surgeries and spinal fusion surgeries. Disc replacement surgery has shown benefits in short-term pain relief, disability, and quality of life compared with spine fusion surgery.

When to Refer

- Progressive worsening of neurologic symptoms, especially leg dominant symptoms.
- Loss of motor function (sensory losses can be followed in the outpatient clinic).

When to Admit

Cauda equina syndrome requires urgent surgical intervention.

Liu C et al. Surgical versus non-surgical treatment for sciatica: systematic review and meta-analysis of randomised controlled trials. BMJ. 2023;381:e070730. [PMID: 37076169]

William J et al. Epidural steroid injections. Phys Med Rehabil Clin N Am. 2022;33:215. [PMID: 35526969]

4. Neck Pain

ESSENTIALS OF DIAGNOSIS

- Chronic neck pain is mostly caused by degenerative joint disease.
- Whiplash often follows a traumatic neck injury.
- Poor posture is often a factor for persistent neck pain.

General Considerations

Most neck pain, especially in older patients, is due to mechanical degeneration involving cervical discs, facet joints, and ligamentous structure. Often there are degenerative changes at adjacent sites. Pain can also come from the supporting neck musculature, which often acts to protect the underlying neck structures. Posture is a very important factor, especially in younger patients. Many work-related neck symptoms are due to poor posture and repetitive motions over time. Acute injuries can also occur secondary to trauma. Whiplash occurs from rapid flexion and extension of the neck and affects 15–40% of people in motor vehicle accidents; chronic pain develops in 5–7%. Neck fractures are serious traumatic injuries acutely and can lead to OA in the long term. Ultimately, degenerative conditions of the neck can result in cervical canal stenosis or neural foraminal stenosis, sometimes affecting underlying neural structures. Focal or multilevel cervical spinal cord compression can lead to cervical myelopathy.

Cervical radiculopathy, usually from the C5–C7 disc levels, can cause neurologic symptoms in the upper extremities. Patients with neck pain may report associated headaches and shoulder pain. Both peripheral nerve entrapment and cervical radiculopathy, known as a "double crush" injury, may develop. Thoracic outlet syndrome, in which there is mechanical compression of the brachial plexus and neurovascular structures with overhead positioning of the arm, should be considered in the differential diagnosis of neck pain. Psychological risk factors for neck pain include stress, anxiety, and sleep problems. Other conditions that can contribute to the development of neck pain include rheumatoid arthritis, autoimmune disorders, age, fibromyalgia, osteomyelitis, neoplasms, polymyalgia rheumatica, compression fractures, pain referred from visceral structures (eg, angina), and functional disorders. Amyotrophic lateral sclerosis, multiple sclerosis, syringomyelia, spinal cord tumors, and Parsonage-Turner syndrome can mimic myelopathy from cervical arthritis.

Clinical Findings

A. Symptoms and Signs

Neck pain may be limited to the posterior region or, depending on the level of the symptomatic joint, may radiate segmentally to the occiput, anterior chest, shoulder girdle, arm, forearm, and hand. It may be intensified by active or passive neck motions. The general distribution of pain and paresthesias corresponds roughly to the involved dermatome in the upper extremity. Progressive hand numbness, weakness, gait disturbance, and loss of fine motor skills are suggestive of cervical myelopathy.

The patient's posture should be assessed, checking for shoulder rolled-forward or head-forward posture as well as scoliosis in the thoracolumbar spine. Patients with discogenic neck pain often report pain with flexion, which causes cervical discs to herniate posteriorly. Extension of the neck usually affects the neural foraminal and facet joints of the neck. Rotation and lateral flexion of the cervical spine should be measured both to the left and the right. Limitation of cervical movements is the most common objective finding.

A detailed neurovascular examination of the upper extremities should be performed, including sensory input to light touch and temperature; motor strength testing, especially the hand intrinsic muscles (thumb extension strength [C6], opponens strength [thumb to pinky] [C7], and finger abductors and adductors strength [C8–T1]); and upper extremity reflexes (biceps, triceps, brachioradialis). Hyperreflexia and a positive Romberg test suggest the gait instability and hand weakness of cervical myelopathy. True cervical radiculopathy symptoms should match an expected dermatomal or myotomal distribution. The Spurling test involves asking the patient to rotate and extend the neck to one side. The clinician can apply a gentle axial load to the neck. Reproduction of the cervical radiculopathy symptoms is a positive sign of nerve root compression. Palpation of the neck is best performed with the patient in the supine position where the clinician can palpate each level of the cervical spine with the muscles of the neck relaxed. One study of patients with cervical radiculopathy, however, showed that only 62.6% of individuals had a concordant dermatomal pattern (where the radicular symptoms matched the involved root) and 67.3% had a standard muscle weakness pattern of the involved nerve.

B. Imaging and Special Tests

Radiographs of the cervical spine include the AP and lateral view. The odontoid view is usually added to rule out traumatic fractures and congenital abnormalities. Oblique views of the cervical spine can provide further information about arthritis changes and assess the neural foramina for narrowing. Plain radiographs can be normal in patients who have suffered an acute cervical strain. Comparative reduction in height of the involved disc space and osteophytes are frequent findings when there are degenerative changes in the cervical spine. Loss of cervical lordosis is commonly seen but is nonspecific.

MRI is the best method to assess the soft tissue structures of the cervical spine (such as the discs, spinal cord, and nerve roots). If the patient has signs of cervical radiculopathy with motor weakness, these more sensitive imaging modalities should be obtained urgently. CT scanning is the most useful method to evaluate bony abnormalities, such as fractures or bone lesions.

Electromyography and nerve conduction studies are useful in differentiating peripheral nerve entrapment syndromes from cervical radiculopathy. However, sensitivity of electrodiagnostic testing for cervical radiculopathy ranges from only 50% to 71%, so a negative test does not rule out nerve root problems.

Treatment

Neck pain can usually be treated conservatively, in the absence of trauma or evidence of infection, malignancy, neurologic findings, or systemic inflammation. More frequent follow-up is recommended for patients when acute, severe symptoms are present early on after an injury. High pain-related disability is a predictor of poor outcome at 1 year even if individuals decline care. A course of specific neck exercises in physical therapy, including stretching, strengthening, and postural exercises, has been demonstrated to relieve symptoms with better short- to medium-term outcomes, although tailored programs were not clearly better than specific neck exercises. A soft cervical collar can be useful for short-term use (up to 1–2 weeks) in acute neck injuries. Ergonomics should be assessed at the workplace and at home. Chiropractic manual manipulation and mobilization can provide short-term benefit for mechanical neck pain. Although the rate of complications is low (5–10 million manipulations), care should be taken whenever there are neurologic symptoms present. Specific patients may respond to use of home cervical traction. NSAIDs are commonly used; opioids may be needed in cases of severe neck pain (Tables 5–5 and 5–6). Muscle relaxants (eg, cyclobenzaprine 5–10 mg orally three times daily) can be used short term if there is muscle spasm or as a sedative to aid in sleeping. Acute radicular symptoms can be treated with neuropathic medications (eg, gabapentin 300–1200 mg orally three times daily), and a short course (5–10 days) of oral prednisone can be considered (starting at 1 mg/kg). Cervical foraminal or facet joint corticosteroid injections can also reduce symptoms. Cervical branch radiofrequency ablation is a second line treatment for chronic neck pain. Surgeries are successful in reducing neurologic symptoms in 80–90% of cases but are still considered as treatments of last resort. Cervical myelopathy often requires surgery. Common surgeries for cervical degenerative disc disease include anterior cervical discectomy with fusion and cervical disc arthroplasty. A 2020 meta-analysis of 11 RCTs showed that beyond 5 years, cervical disc arthroplasty was superior to anterior discectomy and fusion for the treatment of symptomatic cervical disc disease, with better success, lower reoperation rates, and superior longevity.

When to Refer

- Patients with severe symptoms with motor weakness.
- Surgical decompression surgery if the symptoms are severe and there is identifiable, correctable pathology.

UPPER EXTREMITY

1. Lateral & Medial Epicondylosis (Tendinopathy)

ESSENTIALS OF DIAGNOSIS

- Tenderness over the lateral or medial epicondyle.
- Pain with resisted strength testing and passive stretching of the affected tendon and muscle unit.
- Physical therapy and activity modification are more successful than anti-inflammatory treatments.

General Considerations

Tendinopathies involving the wrist extensors, flexors, and pronators are common concerns. The underlying mechanism of injury is repetitive overuse causing microtrauma at the tendon insertion, although acute strain injuries also can occur. The traditional term *epicondylitis* is a misnomer because histologically, tendinosis or degeneration in the tendon is seen rather than acute inflammation. Therefore, these entities should be referred to as *tendinopathy* or *tendinosis*. Lateral epicondylosis involves the wrist extensors, especially the extensor carpi radialis brevis. This is usually caused be lifting with the wrist and the elbow extended. Medial epicondylosis involves the wrist flexors and specifically the pronator teres tendon. Ulnar neuropathy and cervical radiculopathy should be considered in the differential diagnosis.

Clinical Findings

A. Symptoms and Signs

1. Lateral epicondylosis—The patient describes pain with the arm and wrist extended. For example, common concerns include pain while shaking hands, lifting objects, typing, or hitting a backhand in tennis (“tennis elbow”).

2. Medial epicondylosis—Pain during motions in which the arm is repetitively pronated or the wrist is flexed is presenting symptom. This is also known as “golfer’s elbow” due to the motion of turning the hands into pronation during the golf swing.

On examination, tenderness directly over the affected epicondyle is present, especially over the bony prominence where the tendon insertion occurs. The proximal tendon and musculotendinous junction also can be sore. Tendon pain can be reproduced over the epicondyle with resisted wrist extension and third digit extension for lateral epicondylosis and resisted wrist pronation and wrist flexion for medial epicondylosis. The pain is also often reproduced with passive stretching of the affected muscle groups, which can be performed with the arm in extension. It is useful to check the ulnar nerve (located in a groove at the posteromedial elbow) for tenderness as well as to perform a Spurling test for cervical radiculopathy (see Neck Pain, above).

B. Imaging

Radiographs are often normal, although a small traction spur may be present in chronic cases (enthesopathy). Diagnostic investigations are usually unnecessary, unless the patient does not improve after up to 3 months of conservative treatment. At that point, a patient who demonstrates significant disability due to the pain should be assessed with an MRI or ultrasound. Ultrasound and MRI can visualize the tendon and confirm tendinosis or tears.

Treatment

Treatment is usually conservative, including patient education regarding activity modification and management of symptoms. Ice and NSAIDs can help with pain (Table 5–4). The mainstay of treatment is physical therapy exercises. The most important steps are to begin a good stretching program followed by strengthening exercises, particularly eccentric ones. Counterforce elbow braces might provide some symptomatic relief, although there is no published evidence to support their use. If the patient has severe or long-standing symptoms, corticosteroid injections can be considered. A randomized trial showed improvement with corticosteroid injection at 1 month as well as evidence of decreased tendon thickness but no improvement at 3 months. Percutaneous needle tenotomy showed some positive results as an alternative to surgery but lacks demonstrated efficacy in a randomized control study.

Study results are inconsistent about the use of PRP as a treatment for lateral epicondylitis, due to the varied methods of PRP preparations, varying post-injection recommendations, and improvement with placebo injections. A systematic review of PRP for tendinopathy reported a dose-related effect, with higher platelet concentrations demonstrating better outcomes, although the literature regarding tendinopathy is limited. Both leukocyte-rich and leukocyte-poor concentrations of PRP appeared to effectively treat lateral epicondylitis. Conversely, a Cochrane review of 32 studies did not find that autologous blood or PRP injections provided significant improvement over placebo at 3 months or a clinical benefit for pain or function, especially at 6 or 12 months. Compared with ultrasound therapy, extracorporeal shock wave therapy has shown better efficacy for pain relief (as measured with visual analog scales) and better grip strength. However, it is used less commonly than injection treatments of PRP and is still considered second-line therapy.

While individual studies showed some benefits, a Canadian meta-analysis demonstrated that the highest-quality evidence did not support the use of exercise-based physical therapy, corticosteroid injections, PRP, or autologous blood injections, highlighting the challenge of treating these tendinopathies. There is preliminary suggestion of benefit with botulinum toxin injection.

When to Refer

Patients not responding to 6 months of conservative treatment should be referred for an injection procedure (PRP or tenotomy), surgical debridement, or repair of the tendon.

2. Carpal Tunnel Syndrome

ESSENTIALS OF DIAGNOSIS

- Pain, burning, and tingling in the distribution of the median nerve.
- Initially, most bothersome during sleep.
- Later, weakness or atrophy of the thenar eminence.
- Can be caused by repetitive wrist activities.
- Commonly seen during pregnancy, diabetes mellitus, or rheumatoid arthritis.

General Considerations

An entrapment neuropathy, carpal tunnel syndrome is a painful disorder caused by compression of the median nerve between the carpal ligament and other structures within the carpal tunnel. The contents of the tunnel can be compressed by synovitis of the tendon sheaths or carpal joints, recent or malunion fractures, tumors, tissue infiltration, and occasionally congenital syndromes (eg, mucopolysaccharidoses). Risk factors include repetitive hand use or previous wrist injury. The disorder is more common in women and may occur from fluid retention of pregnancy or hormonal changes. Patients with diabetes can get mononeuropathies, possibly related to high glucose levels. Carpal tunnel syndrome can be a feature of Charcot-Marie-Tooth disease; Ehlers-Danlos syndrome; rheumatic diseases, such as rheumatoid arthritis or inflammatory tenosynovitis; infiltrate disorders (myxedema, amyloidosis, sarcoidosis, leukemia, acromegaly); and hyperparathyroidism. The familial type of carpal tunnel syndrome has been associated with collagen, matrix metalloproteinase, and glutathione S-transferase genes.

Clinical Findings

A. Symptoms and Signs

Carpal tunnel syndrome (CTS) presents with numbness, especially at night, waking the patient. Symptoms also are caused by manual activity involving wrist flexion. Aching pain may radiate proximally into the forearm and occasionally proximally to the shoulder and over the neck and chest. Impairment of sensation in the median nerve distribution may or may not be demonstrable. The **Phalen sign** is pain or paresthesia in the distribution of the median nerve when the patient flexes both wrists to 90 degrees for 60 seconds. A timed Phalen test is performed similarly, but the patient reports the time it takes to experience first symptoms up to 120 seconds. If the patient reports symptoms within 10 seconds, this test has a specificity of 96.8% and positive predictive value of 96.6% in predicting abnormal signs of nerve conduction. A **Tinel sign** is tingling or shock-like pain on volar wrist percussion (36–50% sensitive and 77% specific). The **carpal tunnel compression test** (Durkan test) induces numbness and tingling with direct application of pressure over the carpal tunnel for 30 seconds. Muscle weakness or atrophy, especially of the thenar eminence, can appear later than sensory disturbances as compression of the nerve worsens. The CTS-6 tool has good validity and reliability for diagnosing CTS. The six items are (1) numbness predominantly or exclusively over the medial nerve distribution (often the palmar surfaces of the thumb, the index and long fingers, and the radial half of the ring finger); (2) nocturnal numbness; (3) thenar hypotrophy; (4) loss of two-point discrimination < 5 mm; (5) a positive Phalen test; and (6) a positive Tinel sign.

B. Imaging

Ultrasound can demonstrate flattening of the median nerve beneath the flexor retinaculum. Sensitivity of ultrasound for carpal tunnel syndrome is variable but is estimated between 54% and 98%.

C. Special Tests

Electromyography and nerve conduction studies show evidence of sensory conduction delay before motor delay, which can occur in severe cases and is most helpful when the diagnosis is unclear. Electrodiagnosis can provide information on focal median mononeuropathy at the wrist and can classify carpal tunnel syndrome from mild to severe, which may help in worker's compensation cases.

Treatment

Treatment is directed toward relief of pressure on the median nerve. Patients with carpal tunnel syndrome should modify their hand activities if possible. The affected wrist can be splinted in the neutral position for periods up to 3 months, but a series of Cochrane reviews show limited evidence for splinting, exercises, and ergonomic positioning. Moderate evidence supports benefit from several physical therapy and electrophysical modalities (eg, ultrasound therapy and radial extracorporeal shockwave therapy). These modalities provide short-term and mid-term relief of carpal tunnel syndrome symptoms in different studies. Oral corticosteroids or NSAIDs also have shown benefit. There is strong evidence that a corticosteroid injection to the carpal tunnel is more effective in the short term than surgery. Methylprednisolone injections have been found to be more effective at 10 weeks than placebo, but the benefits diminish by 1 year. Knowledge of pertinent anatomy and consistent technique are important to ensuring accurate needle placement during carpal tunnel injection. A systemic review and network meta-analysis examining different injections for CTS found that PRP injections to the carpal tunnel space had the best outcomes and longest results for symptom relief, followed by dextrose injections (prolotherapy), with corticosteroids providing only short-term benefits.

Carpal tunnel release surgery can be beneficial if the patient has a positive electrodiagnostic test, at least moderate symptoms, high clinical probability, unsuccessful nonoperative treatment, and symptoms lasting > 12 months. An RCT showed both corticosteroid injection and surgery resolved symptoms, but only decompressive surgery led to resolution of neurophysiologic changes. Surgery can be done with an open approach or endoscopically, both yielding similar good improvements.

When to Refer

- If symptoms persist > 3 months despite conservative treatment, including the use of a wrist splint.
- If thenar muscle (eg, abductor pollicis brevis) weakness or atrophy develops.

3. Dupuytren Contracture

ESSENTIALS OF DIAGNOSIS

- Benign fibrosing disorder of the palmar fascia.
- Contracture of one or more fingers can lead to limited hand function.

General Considerations

This relatively common disorder is characterized by hyperplasia of the palmar fascia and related structures, with nodule formation and contracture of the palmar fascia. The cause is unknown, but the condition has a genetic predisposition with an estimated heritability of 80% and occurs primarily in White men > 50 years of age, particularly in those of Celtic descent. The incidence is higher among patients with alcohol use disorder and those with chronic systemic disorders (especially cirrhosis). It is also associated with systemic fibrosing syndrome, which includes plantar fibromatosis (10% of patients), Peyronie disease (1–2%), mediastinal and retroperitoneal fibrosis, and

Riedel struma. The onset may be acute, but slowly progressive chronic disease is more common.

Clinical Findings

Dupuytren contracture manifests itself by nodular or cord-like thickening of one or both hands, with the fourth and fifth fingers most commonly affected. The patient may report tightness of the involved digits, with fixed flexion deformity at the metacarpophalangeal (MCP) joint, proximal interphalangeal (PIP) joint, or both with inability to extend the fingers. The contracture may be cosmetically unappealing, but in general it is well tolerated until the MCP fixed flexion deformity reaches 30 degrees or 15 degrees at the PIP joint; intervention is then considered.

Treatment

There are various non-surgical treatments for Dupuytren contracture, including corticosteroids (oral, intramuscular, topical or intralesional); vitamin E; furazolidone; Aminosyn (an amino acid solution); tamoxifen; hyperbaric oxygen; radiotherapy; and physical therapies (ultrasound, splinting, frictional massage, or heat treatment with joint stretching). However, strong evidence for efficacy of these treatments is lacking. If the palmar nodule is growing rapidly, injections of triamcinolone or collagenase into the nodule may be of benefit, while collagenase *Clostridium histolyticum* (CCH) injections lyse collagen, thereby disrupting the contracted cords.

Surgical options, including limited fasciectomy (LF) or percutaneous needle fasciotomy (PNF), are indicated for more severe flexion contractures. Splinting after surgery is beneficial. Recurrence and more adverse events are more likely to occur after surgery than with nonoperative treatments. Overall, surgical treatment is more successful for MCP joints than for PIP joints. Fasciectomies are more successful for severe conditions involving multiple fingers, while PNF is cost-effective and useful for milder cases and for single-digit involvement. A meta-analysis showed similar results in reducing long-term contracture among those treated with LF, PNF, and CCH. However, a multicenter RCT showed that LF performed better than CCH injections, with less contracture recurrence, but with more moderate and severe complications (complications were 5.1% with LF and 1.8% with CCH).

When to Refer

Referral can be considered when one or more digits are affected by severe contractures, which interfere with everyday activities and result in functional limitations.

4. Bursitis

ESSENTIALS OF DIAGNOSIS

- Often occurs around bony prominences where it is important to reduce friction.
- Typically presents with local swelling that is painful acutely.
- Septic bursitis can present without fever or systemic signs.

General Considerations

Inflammation of bursae can lead to fluid accumulation in the synovial membranes overlying bony prominences. Predisposing factors include trauma, infection, or conditions such as chronic rheumatologic diseases (rheumatoid arthritis, gout, pseudogout, SLE), HIV, chronic hygroma (microtraumatic bursopathy), and diabetes. The two common sites are the olecranon and prepatellar bursae; however, others include subdeltoid, ischial, trochanteric, and semimembranosus-gastrocnemius (Baker cyst) bursae. Septic bursitis can result from infection, often preceded by direct trauma or posttraumatic acute bursopathy, or from preexisting conditions such as rheumatoid arthritis or gout.

Clinical Findings

A. Symptoms and Signs

Bursitis presents with focal tenderness and swelling and is less likely to affect range of motion of the adjacent joint. Olecranon or prepatellar bursitis, for example, causes an oval (or, if chronic, bulbous) swelling at the tip of the elbow or knee and does not affect joint motion. A bursa can also become symptomatic when it ruptures. Rupture of a Baker cyst, which occurs in the back of the knee and is usually related to degenerative changes, can cause calf pain and acute swelling that is often confused with DVT.

Tenderness, erythema and warmth, cellulitis, a report of trauma, and overlying skin lesion are more common in **septic bursitis** but can be present in aseptic bursitis as well. Patients with septic bursitis can be febrile but the absence of fever does not exclude infection; one-third of those with septic olecranon bursitis are afebrile.

B. Imaging

Imaging is unnecessary unless there is concern for osteomyelitis, trauma, or other underlying pathology. Baker cysts are best imaged by sonography but are also well imaged by MRI; imaging a presumed Baker cyst can exclude a DVT.

C. Special Tests

Acute swelling and redness at a bursal site call for aspiration to rule out infection especially if the patient either is febrile (temperature > 37.8°C) or has prebursal warmth (temperature difference > 2.2°C) or both (Figure 46–1).

A bursal fluid WBC count of > 1000/mcL (1.0 × 10^9/L) indicates inflammation from infection, rheumatoid arthritis, or gout. The bursal fluid of septic bursitis characteristically contains a purulent aspirate, fluid-to-serum glucose ratio < 50%, WBC count > 3000 cells/mcL (3.0 × 10^9/L), and polymorphonuclear cells > 50%. Most cases are caused by *Staphylococcus aureus* (80–90%) or β-hemolytic streptococci; the Gram stain of bursal fluid is positive in two-thirds, but blood cultures are infrequently positive (0–19%). Elevated serum ESR and CRP can be seen but also occur with crystal-induced bursitis or rheumatoid bursitis.

Treatment

In general, aspiration and corticosteroid injections in mild, nonseptic bursitis should be avoided to reduce complications of iatrogenic infection and skin atrophy. Bursitis caused by trauma can be treated with local heat, rest, NSAIDs early on (Table 5–4), and if very painful or persistent, local corticosteroid injections. Repetitive minor trauma to the olecranon bursa should be eliminated by avoiding resting the elbow on a hard surface or by wearing an elbow pad. For chronic aseptic bursitis or when there are athletic or occupational demands, aspiration with intrabursal corticosteroid injection (methylprednisolone or triamcinolone 40 mg) can be performed. Ultrasound-guided aspiration and injection can improve the accuracy of the procedures. Treatment of a ruptured Baker cyst includes rest, leg elevation, and possibly injection of triamcinolone 40 mg into the knee anteriorly (the knee compartment communicates with the cyst).

Treatment for septic bursitis involves incision and drainage and antibiotics usually delivered intravenously, especially against *S aureus* and β-hemolytic streptococci (see Chapter 35). A clinical reassessment is suggested 3–5 days after the start of antibiotic therapy.

When to Refer

Elective surgical removal can be considered for chronic refractory cases with symptoms affecting activities of daily living.

When to Admit

Septic bursitis requires immediate treatment with intravenous antibiotics and usually incision and draining.

Darrieutort-Laffite C et al. 2023 French recommendations for diagnosing and managing prepatellar and olecranon septic bursitis. Joint Bone Spine. 2023;91:105664. [PMID: 37995861]

HIP

1. Hip Fractures

ESSENTIALS OF DIAGNOSIS

- Internal rotation of the hip is the best provocative diagnostic maneuver.
- Hip fractures should be surgically repaired as soon as possible (within 24 hours).
- Delayed treatment of hip fractures in older adults leads to increased complications and mortality.

General Considerations

Approximately 10 million hip fractures occur globally each year. Hips fracture usually from a fall; high-velocity trauma is needed in younger patients. Stress fractures can occur in athletes or individuals with poor bone mineral density following repetitive loading activities. Osteoporosis, female sex, height > 68 inches, and age > 50 years are risk factors for hip fracture. There is a high mortality rate among older adult patients following hip fracture, with death occurring in 8–10% within 30 days and in approximately 22% within 1 year. Age > 90 years is a risk factor for mortality within 1 year, while male sex, frailty, general anesthesia, high BUN, and high preoperative neutrophil to lymphocyte ratio are risk factors for 90-day mortality.

Clinical Findings

A. Symptoms and Signs

Patients typically report pain in the groin, though pain radiating to the lateral hip, buttock, or knee also can commonly occur. If a displaced fracture is present, the patient will not be able to bear weight and the leg may be externally rotated. Gentle logrolling of the leg with the patient supine helps rule out a fracture. Examination of the hip demonstrates pain with deep palpation in the area of the femoral triangle (similar to palpating the femoral artery). Provided the patient can tolerate it, with the patient supine, the clinician flexes the hip to 90 degrees with the knee flexed to 90 degrees and tests internal and external rotation of the hips on each side. Pain with internal rotation of the hip is the most sensitive test to identify intra-articular hip pathology. Hip flexion, extension, abduction, and adduction strength can be tested.

Patients with hip stress fractures have less pain on physical examination than described previously but typically have pain with weight bearing. The Trendelenburg test can be performed to examine for weakness or instability of the hip abductors, primarily the gluteus medius muscle; the patient balances first on one leg, raising the non-standing knee toward the chest. The clinician can stand behind the patient and observe for dropping of the pelvis and buttock on the non-stance side. Another functional test is asking the patient to hop or jump during the examination. If the patient has a compatible clinical history of pain and is unable or unwilling to hop, then a stress fracture should be ruled out. The back should be carefully examined in patients who report hip discomfort, including examining for signs of sciatica.

Delay of operative intervention for displaced hip fractures leads to an increased risk of perioperative morbidity and mortality. A thorough medical evaluation and treatment should be done to maximize the patient's ability to undergo operative intervention. A patient unable to get up after a fall may have been immobile for hours or even days; rhabdomyolysis, hypothermia, DVT, PE, and other possible sequelae of prolonged immobilization must be excluded.

B. Imaging

Useful radiographic imaging of the hip includes AP views of the pelvis and bilateral hips and frog-leg-lateral views of the painful hip. A CT scan or MRI may be necessary to identify the hip fracture pattern or to exclude non-displaced fractures. Hip fractures are generally described by location, including femoral neck, intertrochanteric, or subtrochanteric.

Treatment

Almost all patients with a hip fracture will require surgery and may need to be admitted to the hospital for pain control while they await surgery. Surgery is recommended within the first 24 hours because studies have shown that delaying surgery 48 hours results in at least twice the rate of major and minor medical complications, including pneumonia, pressure injuries (formerly pressure ulcers), and DVT. High-volume centers have multidisciplinary teams (including orthopedic surgeons, internists, social workers, and specialized physical therapists) to comanage these patients, which improves perioperative medical care and expedites preoperative evaluation leading to reduced costs. Hip fractures can be treated with internal fixation or joint replacement surgery. Cemented total hip arthroplasty has clinically small to large improvements in health-related quality of life and lower mortality at 1 year compared with other hip replacement options. During the months of hip fracture recovery, prevention of pneumonia and functional decline and treatment of cardiac disease can reduce mortality.

Stress fractures in active patients require a period of protected weight bearing and a gradual return to activities, although it may take 4–6 months before a return to normal activities. Femoral neck fractures are commonly treated with hemiarthroplasty or total hip replacement. This allows the patient to begin weight bearing immediately postoperatively. Peritrochanteric hip fractures are treated with open reduction internal fixation, where plate and screw construct or intramedullary devices are used. The choice of implant will depend on the fracture pattern. Since fracture fixation requires the fracture to proceed to union, the patient may need to have protected weight bearing during the early postoperative period. Dislocation, periprosthetic fracture, and avascular necrosis of the hip are complications after surgery. Patients should be mobilized as soon as possible postoperatively to avoid pulmonary complications and pressure injuries. Supervised physical therapy and rehabilitation are important for the patient to regain as much function as possible. Unfortunately, most patients following hip fractures will lose some degree of independence. Patients with hip fracture surgery when compared with elective total hip replacement have been shown to have higher risk of in-hospital mortality.

Prevention

Bone density screening can identify patients at risk for osteopenia or osteoporosis, and treatment can be planned accordingly (see Chapter 30). Consensus is that there is benefit in using bisphosphonates, particularly during the third through fifth years of therapy, with considerations for drug holidays. After 5 years of bisphosphonate use, there is an increased risk for atypical femur fractures. Nutrition and bone health (bone densitometry) should be reviewed with the patient. However, there is no evidence that increasing calcium intake prevents hip fractures. For patients with decreased mobility, systemic anticoagulation should be considered to avoid DVT (see Table 16–14). Fall prevention exercise programs are available for older adult patients at risk for falls and hip fractures. Hip protectors are uncomfortable and have less use in preventing fractures.

When to Refer

- All patients in whom hip fracture is suspected.
- All patients with hip fracture or in whom the diagnosis is uncertain after radiographs.

Hong G et al. Trends in hip fracture surgery in the United States from 2016 to 2021: patient characteristics, clinical management, and outcomes. Br J Anaesth. 2024;133:955. [PMID: 39242278]

Lewis SR et al. Surgical interventions for treating intracapsular hip fractures in older adults: a network meta-analysis. Cochrane Database Syst Rev. 2022;2:CD013404. [PMID: 35156192]

2. Hip Osteoarthritis

ESSENTIALS OF DIAGNOSIS

- Pain deep in the groin on the affected side.
- Swelling.
- Degeneration of joint cartilage.
- Loss of active and passive range of motion in severe OA; normal passive hip adduction makes OA unlikely.

General Considerations

In the United States, the prevalence of OA will grow as the number of persons age > 65 years doubles to > 70 million by 2030. The etiology of OA is often multifactorial, including previous trauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions. Femoroacetabular impingement, which affects younger active patients, is considered an early development of hip OA.

Clinical Findings

A. Symptoms and Signs

OA usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement from damaged cartilage or bone fragments that affect smooth range of motion. Pain can also produce the sensation of "buckling" or "giving way" due to muscle inhibition. As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

Patients report pain deep in the groin on the affected side and have problems with weight-bearing activities such as walking, climbing stairs, and getting up from a chair. They may limp and develop a lurch during their gait, leaning toward the unaffected side as they walk to reduce pressure on the arthritic hip. The most specific findings to identify hip osteoarthritis are squat causing posterior pain, groin pain on passive abduction or adduction, abductor weakness, and decreased passive hip adduction or less passive internal rotation compared with the contralateral leg. The presence of normal passive hip adduction is most useful for suggesting the absence of OA (–LR, 0.25).

B. Imaging

An anterior-posterior weight-bearing radiograph of the pelvis with a lateral view of the symptomatic hip are preferred views for evaluation of hip OA. Joint space narrowing and sclerosis suggest early OA. Findings of femoroacetabular impingement are commonly reported on radiograph reports with arthritic changes and anatomic variations involving the acetabulum and femoral head neck junction. After age 35, MRI of the hips already shows labral changes in almost 70% of asymptomatic persons. Osteophytes near the femoral head or acetabulum and subchondral bone cysts (advanced Kellgren and Lawrence grade), superior or (supero) lateral femoral head migration, and subchondral sclerosis suggest the patient will more likely progress to total hip replacement. However, not all patients with radiographic hip OA have hip or groin pain; the converse is also true.

Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be managed to try to maintain activity level. Conservative treatment for patients with OA includes activity modification, proper footwear, therapeutic exercises (Table 46–6), weight loss, use of assistive devices (such as a cane), and physical therapy with hip-specific, lumbo-pelvic, and core strengthening. A 2014 randomized study, however, found that physical therapy did not lead to greater improvement in pain or function compared with sham treatment in patients with hip OA. Analgesics may be effective in some cases. Corticosteroid injections can be considered for short-term relief of pain; however, hip injections are best performed under fluoroscopic, ultrasound, or CT guidance to ensure accurate injection in the joint. The risk of rapidly progressive degenerative changes following a single low-dose (40 mg or less) triamcinolone injection is low; the risk is higher following a high-dose (80 mg or higher) injection and multiple injections.

Table 46–6. Summary of physical activity for hip or knee osteoarthritis.

- The benefits of physical activity for patients with knee or hip OA include reduced pain and stiffness, increased mobility and physical function, and improvements in mental health, quality of life, and comorbid conditions.
- A prescription for physical activity should be personalized to a patient's physical abilities; affected joint/s; pain; comorbidities; preferences and goals; and access to facilities, programs, and equipment.
- Proven recommendations for a physical activity prescription include:
  - 150 minutes/week of moderate aerobic activity plus 2 days of strengthening exercises
  - As little as 45 minutes/week may be beneficial
  - 6000–10,000 steps/day
- Beneficial activities include walking, cycling, water aerobics or swimming, strength training, stretching, tai chi, yoga, gardening, household chores.
- Patients should be counseled to move more and reduce sedentary time.
- Supervised physical activity sessions, community-based physical activity programs, wearable activity monitors, goal setting, and peer support are techniques to increase adherence to and maintenance of a physical activity routine.

OA, osteoarthritis.

Reproduced with permission from Huffman KF et al. The critical role of physical activity and weight management in knee and hip osteoarthritis: A narrative review. J Rheumatol. 2024;51:224.

B. Surgical

Hip arthroscopy for early osteoarthritis, if there is femoroacetabular impingement, can provide symptom improvement for > 10 years. Unfortunately, when bilateral cartilage defects (acetabular and femoral) are present in more advanced stages of hip osteoarthritis (Tonnis stage 3), hip preservation surgery is contraindicated.

Joint replacement surgeries are effective and cost-effective for patients with significant symptoms, radiologic findings, and functional limitations, providing improvements in pain, function, and quality of life. In considering surgery, underrepresented populations are less willing to undergo total joint replacement, demonstrate worse surgical and functional outcomes, and have less access to hospital choices. Mental health issues including anxiety and depression do not appear to adversely affect a patient's benefit from total hip replacement, although patients with better mental health scores may note greater improvement in patient reported outcomes. There has not been clear clinical benefit of minimally invasive surgery compared with the standard invasive surgery, except for less total blood loss, shorter duration of surgery, and a shorter length of hospital stay.

Hip resurfacing surgery is an alternative for younger patients. Rather than use a traditional artificial joint implant of the whole neck and femur, only the femoral head is removed and replaced. Evidence to date suggests that hip resurfacing is comparable to total hip replacement. The cumulative survival rate of this implant at 10 years is estimated to be 94%. Concerns following resurfacing surgery include the risk of femoral neck fracture and collapse of the head. Chromium metal ion release is elevated postoperatively for the first 6 months. The levels are not elevated past 1 year and do not appear to be a long-term concern. Dislocations were more frequent with total hip arthroplasty than metal-on-metal hip resurfacing: 4.4 versus 0.9 per 1000 person-years, respectively.

Guidelines recommend prophylaxis for venous thromboembolic disease for a minimum of 14 days after arthroplasty of the hip or knee using warfarin, low-molecular-weight heparin, fondaparinux, aspirin, rivaroxaban, dabigatran, apixaban, or portable mechanical compression (see Table 16–14). While bleeding risks are similar, patients taking warfarin are more likely to experience DVT and PE than patients taking rivaroxaban (see Chapter 16).

▶ When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe OA on imaging can be referred for joint replacement surgery.

KNEE

1. Knee Pain

ESSENTIALS OF DIAGNOSIS

- ▶ Effusion can occur with intra-articular pathology (eg, OA, meniscus and cruciate ligament tears).
- ▶ Acute knee swelling (due to hemarthrosis) within 2 hours may indicate ligament injuries or patellar dislocation or fracture.

▶ General Considerations

The knee is the largest joint in the body and is susceptible to injury from trauma, inflammation, infection, and degenerative changes. OA of the knees is common after 50 years of age and can develop due to previous trauma, aging, activities, alignment issues, and genetic predisposition.

Acute hemarthrosis represents bloody swelling that usually occurs within the first 1–2 hours following trauma.

In situations where the trauma may be activity-related and not a result of a fall or collision, the causes of the hemarthrosis most commonly include anterior cruciate ligament (ACL) tear (responsible for > 70% in adults), fracture (patella, tibial plateau, femoral supracondylar, growth plate [physeal]), and patellar dislocation. Meniscal tears are unlikely to cause large hemarthrosis.

Clinical Findings

A. Symptoms and Signs

Duration and rapidity of symptom onset and the mechanism of injury or aggravating symptoms should be determined. Overuse or degenerative problems can occur with stress or compression from sports, hobbies, or occupation. A history of trauma or previous orthopedic problems with, or surgery to, the affected knee should also be specifically queried. Symptoms of infection (fever, recent bacterial infections, risk factors for STIs [such as gonorrhea] or other bacterial infections [such as staphylococcal infection]) should always be elicited.

Common symptoms include the following:

1. Grinding, clicking, or popping with bending may be indicative of OA or the patellofemoral syndrome.
2. “Locking” or “catching” when walking suggests an internal derangement, such as meniscal injury or a loose body in the knee.
3. Intra-articular swelling of the knee or an effusion indicates an internal derangement or a synovial pathology. Large swelling may cause a popliteal (Baker) cyst. Acute swelling within minutes to hours suggests a hemarthrosis, most likely due to an ACL injury, fracture, or patellar dislocation, especially if trauma is involved.
4. Lateral “snapping” with flexion and extension of the knee may indicate inflammation of the iliotibial band.
5. Pain that is worsened with bending and walking down stairs suggests issues with the patellofemoral joint, usually degenerative such as patellar chondromalacia or OA.
6. Pain that occurs when rising after prolonged sitting suggests a problem with tracking of the patella.

A knee joint effusion is characterized by swelling in the hollow or dimple around the patella and distention of the suprapatellar space.

The location of the knee pain combined with specific tests for anatomic structures are frequently sufficient to establish a diagnosis (Tables 46–7 and 46–8).

B. Laboratory Findings

Laboratory testing of aspirated joint fluid, when indicated, can lead to a definitive diagnosis in most patients (see Tables 23–2 and 23–3).

C. Imaging

Knee pain is evaluated with plain (weight-bearing) radiographs and MRI most commonly, but CT and ultrasound are sometimes useful.

Table 46–7. Location of common causes of knee pain.

Medial knee pain
- Medial compartment osteoarthritis
- Medial collateral ligament strain
- Medial meniscal injury
- Anserine bursitis (pain over the proximal medial tibial plateau)

Anterior knee pain
- Patellofemoral syndrome (often bilateral)
- Osteoarthritis
- Prepatellar bursitis (associated with swelling anterior to the patella)
- “Jumper’s knee” (pain at the inferior pole of the patella)
- Septic arthritis
- Gout or other inflammatory disorder

Lateral knee pain
- Lateral meniscal injury
- Iliotibial band syndrome (pain superficially along the distal iliotibial band near the lateral femoral condyle or lateral tibial insertion)
- Lateral collateral ligament sprain (rare)

Posterior knee pain
- Popliteal (Baker) cyst
- Osteoarthritis
- Meniscal tears
- Hamstring or calf tendinopathy

D. Treatment

Treatment of specific etiologies of knee pain is discussed below.

Duong V et al. Evaluation and treatment of knee pain: a review. JAMA. 2023;330:1568. [PMID: 37874571]

2. Anterior Cruciate Ligament Injury

ESSENTIALS OF DIAGNOSIS

- An injury involving an audible pop when the knee buckles.
- Acute swelling immediately (or within 2 hours).
- Instability occurs with lateral movement activities and going down stairs.

General Considerations

The ACL connects the posterior aspect of the lateral femoral condyle to the anterior aspect of the tibia. ACL tears are common with sporting injuries. They can result from both contact (valgus blow to the knee) and non-contact (jumping, pivoting, and deceleration) activities. The patient usually falls down following the injury and has acute swelling, difficulty with weight bearing, and instability. ACL injuries are common in skiing, soccer, football, and basketball among young adolescents and middle-aged patients. Prepubertal and older patients usually sustain fractures instead of ligamentous injuries.

Table 46–8. Knee examination.

Maneuver	Description
Inspection	Examine for the alignment of the lower extremities (varus, valgus, knee recurvatum), ankle eversion and foot pronation, gait, and "SEADS" (*s*welling, *e*rythema, *a*trophy, *d*eformity, *s*urgical scars).
Palpation	Include important landmarks: patellofemoral joint, medial and lateral joint lines (especially posterior aspects), pes anserine bursa, distal iliotibial band, and Gerdy tubercle (iliotibial band insertion).
Range of motion testing  	Check range of motion actively (patient performs) and passively (clinician performs), especially with flexion and extension of the knee normally 0–10 degrees of extension and 120–150 degrees of flexion.
Knee strength testing	Test resisted knee extension and knee flexion strength manually.
Ligament Stress Testing	
Lachman test  	Performed with the patient lying supine and the knee flexed to 20–30 degrees. The examiner grasps the distal femur from the lateral side, and the proximal tibia with the other hand on the medial side. With the knee in neutral position, stabilize the femur, and pull the tibia anteriorly using a similar force to lift a 10- to 15-pound weight. **Positive test:** Excessive anterior translation of the tibia compared with the other side indicates injury to the anterior cruciate ligament.
Anterior drawer 	Performed with the patient lying supine and the knee flexed to 90 degrees. The clinician stabilizes the patient's foot by sitting on it and grasps the proximal tibia with both hands around the calf and pulls anteriorly. **Positive test:** There is anterior cruciate ligament laxity compared with the unaffected side.

(*continued*)

Table 46–8. Knee examination. (continued)

Maneuver	Description
Pivot shift 	Used to determine the amount of rotational laxity of the knee. The patient is examined while lying supine with the knee in full extension. It is then slowly flexed while applying internal rotation and a valgus stress. **Positive test:** The clinician feels for a subluxation at 20–40 degrees of knee flexion. (The patient must remain very relaxed to have a positive test.)
Valgus stress 	Performed with the patient lying supine. The clinician should stand on the outside of the patient's knee. With one hand, the clinician should hold the ankle while the other hand is supporting the leg at the level of the knee joint. A valgus stress is applied at the ankle to determine pain and laxity of the medial collateral ligament. The test should be performed at both 30 degrees and 0 degrees of knee extension. **Positive test:** Pain and laxity of the medial collateral ligament with valgus stress. The test results can be graded from 1 to 3. Grade 1 is when the patient has pain with the valgus stress test but no instability. With grade 2 injuries, the patient has pain, and the knee shows instability at 30 degrees of knee flexion. In grade 3 injuries, the patient has marked instability but not much pain.

(*continued*)

Table 46–8. Knee examination. (continued)

Maneuver	Description
Varus stress 	Performed with the patient lying supine. For the right knee, the clinician should be standing on the right side of the patient. The left hand of the examiner should be holding the ankle while the right hand is supporting the lateral thigh. A varus stress is applied at the ankle to determine pain and laxity of the lateral collateral ligament. The test should be performed at both 30 degrees and 0 degrees of knee flexion. **Positive test:** Pain and laxity of the lateral collateral ligament with varus stress. The test results can be graded from 1 to 3. Grade 1 is when the patient has pain with the varus stress test but no instability. With grade 2 injuries, the patient has pain, and the knee shows instability at 30 degrees of knee flexion. In grade 3 injuries, the patient has marked instability but not much pain.
Meniscal Signs	
McMurray test	Performed with the patient lying supine. The clinician flexes the knee until the patient reports pain. For this test to be valid, it must be flexed pain-free beyond 90 degrees. **Positive test:** The clinician externally rotates the patient's foot and then extends the knee while palpating the medial knee for "click" in the medial compartment of the knee or pain reproducing pain from a meniscus injury. To test the lateral meniscus, the same maneuver is repeated while rotating the foot internally (53% sensitivity and 59–97% specificity).
Modified McMurray 	Performed with the patient lying supine and the hip flexed to 90 degrees. The knee is then flexed maximally with internal or external rotation of the lower leg. The knee can then be rotated with the lower leg in internal or external rotation to capture the torn meniscus underneath the condyles. **Positive test:** Pain over the joint line while the knee is being flexed and internally or externally rotated.

(*continued*)

Table 46–8. Knee examination. (continued)

Maneuver	Description
Modified McMurray (Cont.) 	
Thessaly test 	Performed with the patient standing on one leg with knee slightly flexed. The patient is asked to twist the knee while standing on one leg. **Positive test:** Pain is elicited during twisting motion.

Clinical Findings

A. Symptoms and Signs

Acute ACL injuries usually lead to acute swelling of the knee, causing difficulty with motion. After the swelling has resolved, the patient can walk with a "stiff-knee" gait or quadriceps avoidance gait because of the instability. Patients describe symptoms of instability while performing side-to-side maneuvers or descending stairs. Stability tests assess the amount of laxity of the knee while performing these maneuvers. The Lachman test is 84–87% sensitive and 93% specific, and the anterior drawer test is 48% sensitive and 87% specific for ACL laxity compared with the other side (Table 46–8). The pivot shift test is 79% sensitive and 9% specific for rotational laxity of the knee (Table 46–8).

B. Imaging

Plain radiographs are usually negative in ACL tears but are useful to rule out fractures. A small avulsion injury can sometimes be seen over the lateral compartment of the knee ("Segond" fracture) and is pathognomonic of an ACL injury. An ACL injury that avulsed the tibial spine can be seen in radiographs. MRI is the best tool to diagnose ACL tears and associated articular and meniscal cartilage issues. It has > 95% sensitivity and specificity for ACL tears.

Treatment

Most young and active patients will require surgical reconstruction of the ACL. Some data suggest that reconstruction within 5 months of the tear has better outcomes. However, a small, randomized trial suggested that acute ACL injuries can be treated nonoperatively and delayed ACL reconstruction had similar outcomes to acute ACL reconstructions. Patients for whom the reconstruction is delayed, however, have more cartilage or meniscus problems at the time of surgery. Common surgical techniques use the patient's own tissue, usually the patellar or hamstring tendons (autograft), or use a cadaver graft (allograft) to arthroscopically reconstruct the torn ACL; allografts have a higher failure rate when compared with autografts, especially for younger patients. Recovery from surgery usually requires 9–12 months.

Nonoperative treatments are usually reserved for older patients or those with a very sedentary lifestyle. Physical therapy can focus on hamstring strengthening and core stability. An ACL brace can help stability. Longitudinal studies have demonstrated that nonoperative management of an ACL tear can lead to a higher incidence of meniscus tears. Cost-analysis studies have shown that early ACL reconstruction can be more beneficial than nonoperative treatment and delayed subsequent surgeries.

When to Refer

- Almost all ACL tears should be referred to an orthopedic surgeon for evaluation.
- Individuals with instability in the setting of a chronic ACL tear (> 6 months) should be considered for surgical reconstruction.
- Patients with an ACL tear and associated meniscus or articular injuries may benefit from surgery to address the other injuries.

3. Collateral Ligament Injury

ESSENTIALS OF DIAGNOSIS

- Caused by a valgus or varus blow or stress to the knee.
- Pain and instability in the affected area.
- Limited range of motion.

General Considerations

The medial collateral ligament (MCL) is the most commonly injured ligament in the knee. It is usually injured with a valgus stress to the partially flexed knee. It can also occur with a blow to the lateral leg. The MCL is commonly injured with acute ACL injuries. The lateral collateral ligament (LCL) is less commonly injured, but this can occur with a medial blow to the knee. Since both collateral ligaments are extra-articular, injuries to these ligaments may not lead to any intra-articular effusion. Affected patients may have difficulty walking initially, but this can improve when the swelling decreases.

Clinical Findings

A. Symptoms and Signs

The main clinical findings for patients with collateral ligament injuries are pain along the course of the ligaments. The patient may have limited range of motion due to pain, especially during the first 2 weeks following the injury. The best tests to assess the collateral ligaments are the varus and valgus stress tests (Table 46–8). The knee is often unstable at both 30 degrees and 0 degrees of knee flexion. The overall sensitivity of the tests is 86–96%.

B. Imaging

Radiographs are usually nondiagnostic except for avulsion injuries. However, radiographs should be used to rule out fractures that can occur with collateral ligament injuries. MRI is usually not required for MCL injuries; however, it can be obtained to evaluate associated cruciate ligament injuries, menisci, or posterolateral corner injuries. However, lateral-sided injuries should have an MRI to evaluate the severity of injury and guide treatment.

Treatment

Most MCL injuries can be treated with protected weight bearing and physical therapy. For grade 1 and 2 injuries, the patient can usually bear weight as tolerated with full range of motion (see Table 46–8 for definitions of grade 1–3 injuries of the knee). A hinged knee brace can be given to patients with grade 2 MCL tears to provide stability. Early physical therapy is recommended to protect range of motion and muscle strength. Grade 3 MCL injuries require long leg braces to provide stability. Patients can weight-bear, but only with the knee locked in extension with a brace.

The motion can then be increased with the brace unlocked. Grade 3 injuries can take up to 6–8 weeks to heal. MCL injuries rarely need surgery. MCL repair or reconstruction is considered in higher-grade injuries, in large bone avulsions where the displaced fibers of the MCL prevent healing (Stener-like lesion), or in patients with chronic pain who fail nonoperative management. LCL injuries are less common but are usually associated with other ligament injuries (such as ACL and posterior cruciate ligament [PCL]). LCL injuries do not recover well with nonoperative treatment and usually require urgent surgical repair or reconstruction.

When to Refer

- Symptomatic instability with chronic MCL tears or acute MCL tears with other ligamentous injuries.
- LCL or posterolateral corner injuries require urgent surgical repair or reconstruction (within 1 week).

Mowers C et al. Medial collateral ligament reconstruction and repair show similar improvement in outcome scores, but repair shows higher rates of knee stiffness and failure: a systematic review. Arthroscopy. 2023;39:2231. [PMID: 36898592]

4. Posterior Cruciate Ligament Injury

ESSENTIALS OF DIAGNOSIS

- Usually follows anterior trauma to the tibia, such as a dashboard injury from a motor vehicle accident.
- The knee may freely dislocate and reduce.
- One-third of multi-ligament injuries involving the PCL have neurovascular injuries.

General Considerations

The PCL is the strongest ligament in the knee. PCL injuries usually represent significant trauma and are highly associated with multi-ligament injuries and knee dislocations. More than 70–90% of PCL injuries have associated injuries to the posterolateral corner, MCL, and ACL. Neurovascular injuries occur in up to one-third of all knee dislocations or PCL injuries. There should be high suspicion for neurovascular injuries and a thorough neurovascular examination of the limb should be performed. Most acute PCL injuries should be evaluated by a specialist.

Clinical Findings

A. Symptoms and Signs

Most patients with acute injuries have difficulty with ambulation. Patients with chronic PCL injuries can ambulate without gross instability but may describe subjective "looseness" and often report pain and dysfunction, especially with bending. Clinical examinations of PCL injuries include the "sag sign"; the patient is placed supine and both hips and knees are flexed to 90 degrees. Because of gravity, the posterior cruciate ligament-injured knee will have an obvious set-off at the anterior tibia that is "sagging" posteriorly. The PCL ligament can also be examined using the posterior drawer test; the patient is placed supine with the knee flexed to 90 degrees. In a normal knee, the anterior tibia should be positioned about 10 mm anterior to the femoral condyle. The clinician can grasp the proximal tibia with both hands and push the tibia posteriorly. The movement, indicating laxity and possible tear of the PCL, is compared with the uninjured knee (90% sensitivity and 99% specificity). A PCL injury is sometimes mistaken for an ACL injury during the anterior drawer test since the tibia is subluxed posteriorly in a sagged position and can be abnormally translated forward, yielding a false-positive test for an ACL injury (Table 46–8). Pain, swelling, pallor, and numbness in the affected extremity may suggest a knee dislocation with possible injury to the popliteal artery. If the lateral knee is unstable with varus stress testing (Table 46–8), the patient should be assessed for a posterolateral corner injury, which consists of injuries to the LCL, popliteus tendon, and popliteofibular ligament. Injuries to the posterolateral corner usually require urgent surgical treatment.

B. Imaging

Radiographs are often nondiagnostic but are required to diagnose any fractures. MRI is used to diagnose PCL and other associated injuries.

Treatment

Isolated PCL injuries can be treated nonoperatively. Acute injuries are usually immobilized using a knee brace with the knee extension; the patient uses crutches for ambulation. Physical therapy can help achieve increased range of motion and improved ambulation. Many PCL injuries are associated with other injuries and may require operative reconstruction.

When to Refer

- The patient should be seen urgently within 1–2 weeks.
- Posterolateral corner injury requires urgent surgical reconstruction.
- Isolated PCL tears may require surgery if the tear is complete (grade 3) and the patient is symptomatic.

Moatshe G et al. Rates of subjective failure after both isolated and combined posterior cruciate ligament reconstruction: a study from the Norwegian Knee Ligament Registry 2004-2021. Am J Sports Med. 2024;52:1491. [PMID: 38551134]

5. Meniscus Injuries

ESSENTIALS OF DIAGNOSIS

- Patient may or may not report an injury.
- Joint line pain and pain with deep squatting are the most sensitive signs.
- Difficulty with knee extension suggests an internal derangement that should be evaluated urgently with MRI.

General Considerations

The menisci act as shock absorbers within the knee. Most meniscus injuries occur with acute injuries (usually in younger patients) or repeated microtrauma, such as squatting or twisting (usually in older patients).

Clinical Findings

A. Symptoms and Signs

Patients may have an antalgic (painful) gait and difficulty with squatting. They may report catching or locking of the meniscal fragment. Patients can usually point out the area of maximal tenderness along the joint line. Swelling usually occurs during the first 24 hours after the injury or later. Meniscus tears rarely lead to the immediate swelling that is commonly seen with fractures and ligament tears. Meniscus tears are commonly seen in arthritic knees. However, it is often unclear whether the pain is coming from the meniscus tear or the arthritis.

Physical findings may include effusion or joint line tenderness along the medial or lateral side of the knee (83% sensitivity; 83% specificity). Provocative tests, including the McMurray test, the modified McMurray test, and the Thessaly test, can be performed to confirm the diagnosis (Table 46–8). Most symptomatic meniscus tears cause pain with deep squatting and when waddling (performing a "duck walk").

B. Imaging

Radiographs are usually normal but may show joint space narrowing, early OA changes, or loose bodies. MRI of the knee is the best diagnostic tool for meniscal injuries (93% sensitivity and 95% specificity).

Treatment

Conservative treatment can be used for degenerative tears in older patients. The treatment is similar as for patients with mild knee OA, including analgesics and physical therapy for strengthening and core stability. An RCT showed that physical therapy compared with arthroscopic partial meniscectomy had similar outcomes at 6 months. However, 30% of the patients who were assigned to physical therapy alone underwent surgery within 6 months.

Randomized studies have shown that arthroscopic surgery has no benefit over sham operations in patients who have degenerative meniscal tears, especially with imaging showing signs of osteoarthritis. Another RCT found that patients with degenerative meniscus tears but no signs of arthritis on imaging treated conservatively with supervised exercise therapy had similar outcomes to those treated with arthroscopy at 2-year follow-up. Overall, patients can be treated with supervised exercise therapy first, and if they do not respond to nonoperative treatment, then meniscus surgery can be considered. Acute tears in young and active patients with clinical signs of internal derangement (catching and swelling) and without signs of arthritis on imaging or patients with acute mechanical locking with a displaced meniscus can be best treated arthroscopically with meniscus repair or debridement. There is also evidence that untreated meniscus root tears (tears where the meniscus attaches to the back or posterior aspect of the tibia) can lead to accelerated osteoarthritic changes. Surgical treatment is recommended for large displaced and/or bucket handle meniscus tears, and for acute meniscus root tears to restore knee function and reduce cartilage breakdown.

When to Refer

- If the patient has symptoms of internal derangement suspected as meniscus injury. The patient should receive an MRI to confirm the injury.
- If the patient cannot extend the knee due to a mechanical block, the patient should be evaluated as soon as possible. Certain shaped tears on MRI, such as bucket handle tears or meniscus root injuries, are amenable to meniscal repair surgery.
- If the patient has not responded to physical therapy and nonoperative treatment and continues to have symptoms related to the torn meniscus.

Flores SE et al. Prognostic factors on preoperative MRI for patient-reported outcomes after posterior medial meniscus root repair. Orthop J Sports Med. 2024;12:23259671241263648. [PMID: 39165327]

Kopf S et al. Management of traumatic meniscus tears: the 2019 ESSKA meniscus consensus. Knee Surg Sports Traumatol Arthrosc. 2020;28:1177. [PMID: 32052121]

6. Patellofemoral Pain

ESSENTIALS OF DIAGNOSIS

- Pain experienced with bending activities (kneeling, squatting, climbing stairs).
- Lateral deviation or tilting of the patella in relation to the femoral groove.

General Considerations

Patellofemoral pain, also known as anterior knee pain, chondromalacia, or "runner's knee," describes any pain involving the patellofemoral joint. The pain affects any or all of the anterior knee structures, including the medial and lateral aspects of the patella as well as the quadriceps and patellar tendon insertions. Forces on the patellofemoral joint increase up to three times body weight as the knee flexes to 90 degrees (eg, climbing stairs), and five times body weight when going into full knee flexion (eg, squatting). Abnormal patellar tracking during flexion can lead to abnormal articular cartilage wear and pain. When the patient has ligamentous hyperlaxity, the patella can sublux out of the groove, usually laterally. Patellofemoral pain is also associated with muscle strength and flexibility imbalances as well as altered hip and ankle biomechanics.

Clinical Findings

A. Symptoms and Signs

Patients usually report pain in the anterior knee with bending and less commonly in full extension. Pain from this condition is localized under the patella but can sometimes be referred to the posterior knee or over the medial or lateral inferior patella. Symptoms may begin after trauma or after repetitive physical activity, such as running and jumping. With patellar maltracking, palpable and sometimes audible crepitus can occur.

Intra-articular swelling usually does not occur unless articular cartilage defects or OA changes develop. On physical examination, it is important to palpate the articular surfaces of the patella. The clinician can use one hand to move the patella laterally and use the fingertips of the other hand to palpate the lateral undersurface of the patella. Patellar mobility can be assessed by medially and laterally deviating the patella (deviation by one-quarter of the diameter of the patella is considered normal; greater than one-half the diameter suggests excessive mobility). The apprehension sign suggests instability of the patellofemoral joint and is positive when the patient becomes apprehensive when the patella is deviated laterally. The patellar grind test is performed by grasping the knee superior to the patella and pushing it downward with the patient supine and the knee extended, pushing the patella inferiorly. The patient is asked to contract the quadriceps muscle to oppose this downward translation, with reproduction of pain or grinding being the positive sign for chondromalacia of the patella. There are two common presentations: (1) patients whose ligaments and patella are too loose (hypermobility); and (2) patients who have soft tissues that are too tight, leading to excessive pressure on the joint.

Quadriceps strength and hip stabilizers can be evaluated by having the patient perform a one-leg squat without support. Normally, with a one-leg squat, the knee should align over the second metatarsal ray of the foot. Patients who are weak may display poor balance, with dropping of the pelvis (similar to a positive hip Trendelenburg sign) or excessive internal rotation of the knee medially.

B. Imaging

Diagnostic imaging has limited use in younger patients and is more helpful in older patients to assess for OA or to evaluate patients who do not respond to conservative treatment. Radiographs may show lateral deviation or tilting of the patella in relation to the femoral groove. MRI may show thinning of the articular cartilage but is not clinically necessary, except prior to surgery or to exclude other pathology.

Treatment

A. Conservative

For symptomatic relief, use of local modalities such as ice and anti-inflammatory medications can be beneficial. If the patient has signs of patellar hypermobility, physical therapy exercises are useful to strengthen the quadriceps (especially the vastus medialis obliquus muscle) to help stabilize the patella and improve tracking (keeping the patella from shifting laterally or medially when the leg bends or straightens). There is good evidence that exercise therapy for patellofemoral pain syndrome may result in clinically important reduction in pain and improvement in functional ability. Lower quality research supports that hip and knee exercises are better than knee exercises alone. Strengthening the quadriceps and the posterolateral hip muscles such as the hip abductors that control rotation at the knee are recommended. Support for the patellofemoral joint can be provided by use of a patellar stabilizer brace or special taping techniques. Correcting lower extremity alignment (with appropriate footwear or over-the-counter orthotics) can help improve symptoms, especially if the patient has pronation or high-arched feet. If the patient demonstrates tight peripatellar soft tissues, special focus should be put on stretching the hamstrings, iliotibial band, quadriceps, calves, and hip flexors. The goal of conservative treatment is improvement in movement pattern to reduce load on the patellofemoral joint, focusing on hip and knee exercises and internal feedback.

B. Surgical

Surgery is rarely needed and is considered a last resort for patellofemoral pain. Procedures performed include lateral release or patellar realignment surgery. Surgery is indicated when patients have recurrent patella instability or dislocations.

When to Refer

Patients with persistent symptoms despite a course of conservative therapy.

7. Knee Osteoarthritis

ESSENTIALS OF DIAGNOSIS

- Degeneration of joint cartilage.
- Pain with bending or twisting activities.
- Swelling.
- Loss of active and passive range of motion in severe OA.

General Considerations

The incidence of knee OA in the United States is 240 per 100,000 person-years; the prevalence of OA will likely grow to 70 million persons by 2030 as the number of persons age > 65 increases. The etiology of OA is often multifactorial including previous trauma, repetitive microtrauma, prior high-impact activities, genetic factors, obesity, and rheumatologic or metabolic conditions.

Clinical Findings

A. Symptoms and Signs

OA usually causes pain in the affected joint with loading of the joint or at the extremes of motion. Mechanical symptoms—such as swelling, grinding, catching, and locking—suggest internal derangement, which is indicated by damaged cartilage or bone fragments that affect the smooth range of motion expected at an articular joint. Pain can also produce the sensation of "buckling" or "giving way" due to muscle inhibition (Table 46–4) (Table 46–5) (Table 46–6). As the joint degeneration becomes more advanced, the patient loses active range of motion and may lose passive range of motion as well.

As the condition worsens, patients with knee OA have an increasingly limited ability to walk. Symptoms include pain with bending or twisting activities and going up and down stairs. Swelling, limping, and pain while sleeping are common symptoms of OA, especially as it progresses.

B. Imaging

The most commonly recommended radiographs include bilateral weight-bearing 45-degree bent knee posteroanterior, lateral, and patellofemoral joint views (Merchant view). Radiographic findings include diminished width of the articular cartilage causing joint space narrowing, subchondral sclerosis, presence of osteophytes, and cystic changes in the subchondral bone. MRI of the knee is most likely unnecessary unless other pathology is suspected, such as ischemic osteonecrosis of the knee.

Treatment

A. Conservative

Changes in the articular cartilage are irreversible. Therefore, a cure for the diseased joint is not possible, although symptoms or structural issues can be addressed to try to maintain activity level. Conservative treatment for all patients with OA includes activity modification, therapeutic exercises, and weight loss. Lifestyle modifications also include proper footwear and avoidance of high-impact activities. Optimal exercise programs for knee OA should focus on improving aerobic capacity, quadriceps muscle strength, or lower extremity performance; ideally, the programs should occur three times a week and be supervised (Table 46–6).

Use of a cane in the hand opposite to the affected side is mechanically advantageous. Knee sleeves or braces provide some improvement in subjective pain symptoms most likely due to improvements in neuromuscular function. If patients have unicompartmental OA in the medial or lateral compartment, joint unloader braces are available to offload the degenerative compartment. Cushioning footwear and appropriate orthotics or shoe adjustments are useful for reducing impact to the lower extremities.

The first-line recommendation for pain management is topical nonsteroidal medication (eg, diclofenac gel) (Table 5–4). Alternatively, topical capsaicin may be effective. Oral medications that have been shown to significantly improve pain include ibuprofen, naproxen, diclofenac, and celecoxib. If a traditional NSAID is indicated, the choice should be based on cost, side-effect profile, and adherence (Table 5–4). For patients with increased risk of GI bleeding, a cyclooxygenase (COX)-2 inhibitor (ie, celecoxib) or adding a PPI to the NSAID is recommended. A COX-2 inhibitor is no more effective than traditional NSAIDs; it may offer short-term, but probably not long-term, advantage in preventing GI complications. Acetaminophen has been shown to be less effective than NSAIDs but can be used in patients when NSAID use is contraindicated. Tramadol can be used appropriately in patients with severe OA as alternative to NSAIDs, while opioid use is discouraged. Turmeric supplements have shown some benefit for OA. Glucosamine and chondroitin sulfate are supplements that have been widely used and marketed for OA. Despite some initial promise, the best-controlled studies indicate these supplements are ineffective as analgesics in OA. However, they have minimal side effects and may be appropriate if the patient experiences subjective benefit. Genicular nerve block and radiofrequency ablation are affective for pain management over 24 months in some cases, although this is usually a later treatment after injection therapies.

Traditionally, knee joint corticosteroid injections are options to help reduce pain and inflammation and can provide short-term pain relief, usually lasting about 6–12 weeks. While intra-articular triamcinolone is still commonly used in knee arthritis, an RCT showed that 2 years of intra-articular triamcinolone every 3 months, compared with intra-articular saline, resulted in significantly greater quantitative cartilage volume loss by MRI and no significant difference in knee pain. In general, regular use of corticosteroid injections for long-term treatment of knee osteoarthritis should be avoided.

Viscosupplementation using injections of hyaluronic acid–based products is controversial. Because reviews suggested that viscosupplementation has a questionably clinically relevant effect size and an increased risk of nonthreatening adverse events, the American Academy of Orthopedic Surgeons recommended that viscosupplementation should not be used in the treatment of knee OA.

Leukocyte-poor PRP injections remain the most common orthobiologic treatment, as PRP contains high concentration of platelet-derived growth factors that regulate some biologic processes in tissue repair. There is a potential dose–response relationship between platelet dose and PRP effectiveness for knee OA treatment; the suggested optimal threshold is > 10 billion platelets for favorable clinical outcomes.

B. Surgical

Knee joint replacement surgery for advanced OA is very successful and cost-effective for patients with significant symptoms or functional limitations, providing improvements in pain, function, and quality of life. Practice guidelines from the American College of Rheumatology recommend joint replacement surgery for symptomatic moderate to severe osteoarthritis or advanced symptomatic osteonecrosis. They recommend delaying surgery for patients with diabetes until good glycemic control is achieved and for patients who smoke until they adequately decrease or cease nicotine use. In patients with obesity, the ACR strongly encourages weight reduction before surgery, counseling on how to lose weight, and education on the increased risk of medical and surgical complications due to obesity. Long-term series describe a > 95% survival rate of the implant at 15 years. Minimally invasive surgeries and computer-assisted navigation during operation are being investigated as methods to improve techniques (eg, accurate placement of the hardware implant) and to reduce complication rates; however, major improvements have yet to be demonstrated. Two randomized trials demonstrated that arthroscopy does not improve outcomes at 1 year over placebo or routine conservative treatment of OA.

Knee realignment surgery, such as high tibial osteotomy or partial knee replacement surgery, is indicated in patients younger than age 60 with unicompartmental OA who would benefit from delaying total knee replacement.

When to Refer

Patients with sufficient disability, limited benefit from conservative therapy, and evidence of severe OA can be referred for joint replacement surgery.

Hannon CP et al. 2023 American College of Rheumatology and American Association of Hip and Knee Surgeons Clinical Practice Guideline for the optimal timing of elective hip or knee arthroplasty for patients with symptomatic moderate-to-severe osteoarthritis or advanced symptomatic osteonecrosis with secondary arthritis for whom nonoperative therapy is ineffective. Arthritis Care Res (Hoboken). 2023;75:2227. [PMID: 37743767]

ANKLE INJURIES

1. Inversion Ankle Sprains

ESSENTIALS OF DIAGNOSIS

- Most ankle injuries involve plantar flexion and inversion sprains affecting the lateral ligaments.
- The anterior drawer test and talar tilt test are the best tests to grade ligament injury severity.
- Consider chronic ankle instability or associated injuries if pain persists for > 3 months following an ankle sprain.

General Considerations

Ankle sprains (stretch or tear of ankle ligaments) are the most common sports injuries seen in outpatient clinics. While common, ankle sprains can negatively affect quality of life. One study found that respondents with a history of ankle sprain had higher BMI and overall pain, lower physical activity, and worse health-related quality of life scores than non-injured controls. The most common mechanism of injury is a plantar flexion and inversion sprain, which injures the anterior talofibular (ATF) ligament followed by the calcaneofibular (CF) ligament. Other injuries that can occur with inversion ankle injuries are listed in Table 46–9. Women appear to sustain an inversion injury more frequently than men. Chronic ankle instability is defined as persistent pain, swelling, and "giving way" in combination with recurrent sprains for at least 12 months after the initial ankle sprain. Chronic ankle instability can occur in up to 43% of ankle sprains despite physical therapy, which makes appropriate attention to acute ankle sprains important.

Table 46–9. Injuries associated with ankle sprains.

Ligaments
Subtalar joint sprain
Sinus tarsi syndrome (ongoing anterolateral posttraumatic ankle pain)
Syndesmotic (distal tibiofibular ligamentous) sprain
Deltoid sprain
Lisfranc (tarsometatarsal bony or ligamentous) injury

Tendons
Posterior tibial tendon strain
Peroneal tendon subluxation

Bones
Osteochondral talus injury
Lateral talar process fracture
Posterior impingement (os trigonum)
Fracture at the base of the fifth metatarsal
Jones fracture (between base and middle of fifth metatarsal)
Salter (growth plate) fracture (fibula)
Ankle fractures

Clinical Findings

A. Symptoms and Signs

Patients usually report "turning the ankle" during a fall or after landing on an irregular uneven surface such as a hole or an opponent's foot. Symptoms following a sprain include localized pain and swelling over the lateral aspect of the ankle, difficulty weight bearing, and limping. On examination, there may be swelling or bruising over the lateral aspect of the ankle. The anterior, inferior aspect below the lateral malleolus is most often the point of maximal tenderness consistent with ATF and CF ligament injuries. The swelling may limit motion of the ankle.

B. Stress Tests

1. Anterior drawer test—For this ankle stress test, the clinician keeps the foot and ankle in the neutral position with the patient sitting, then uses one hand to fix the tibia and the other to hold the patient's heel and draw the ankle forward. Normally, there may be approximately 3 mm of translation until an endpoint is felt. A positive test includes increased translation of one foot compared with the other with loss of the endpoint of the ATF ligament.

2. Subtalar tilt test—This stress test is performed with the foot in the neutral position with the patient sitting. The clinician uses one hand to fix the tibia and the other to hold and invert the calcaneus. Normal inversion at the subtalar joint is approximately 30 degrees. A positive test consists of increased subtalar joint inversion by > 10 degrees on the affected side with loss of endpoint for the CF ligament. To grade the severity of ankle sprains, no laxity on stress tests is considered a grade 1 injury, laxity of the ATF ligament on anterior drawer testing but a negative tilt test is a grade 2 injury, and both positive drawer and tilt tests signify a grade 3 injury. Difficulty jumping and landing within 2 weeks from the acute ankle sprain, abnormal postural or hip muscle control, or ligamentous laxity noted 8 weeks after injury are poor prognostic signs.

C. Imaging

Routine ankle radiographic views include the AP, lateral, and oblique (mortise) views. Less common views requested include the calcaneal view and subtalar view. The **Ottawa Ankle Rules** remain the best clinical prediction rules to guide the need for radiographs and have an 86–99% sensitivity and a 97–99% negative predictive value for ankle pathology. If the patient is unable to bear weight immediately in the office setting or emergency department for four steps, then the clinician should check for (1) bony tenderness at the posterior edge of the medial or lateral malleolus and (2) bony tenderness over the navicular (medial midfoot) or at the base of the fifth metatarsal. If either malleolus demonstrates pain or deformity, then ankle radiographs should be obtained. If the foot has bony tenderness, obtain foot radiographs. An MRI is helpful when considering the associated injuries.

Treatment

Immediate treatment of an ankle sprain follows the MICE mnemonic: *m*odified activities, *i*ce, *c*ompression, and *e*levation. NSAIDs are useful in reducing pain and swelling in the first 72 hours following the ankle sprain; notably, NSAIDs, paracetamol, and opioids have similar results in reducing early pain. Subsequent treatment involves protected weight bearing with crutches and an ankle stabilizer brace, especially for grade 2 and 3 injuries. Early functional and dynamic rehabilitation exercises result in a shorter time to return to sport, increased functional performance, and decreased self-reported reinjury. Patients should be encouraged to do a program of exercises or physical therapy. Manual therapy with early ankle mobilization and stretching treatments is important to restore range of motion, especially ankle dorsiflexion. Proprioception and balance exercises (eg, "wobble board") can help restore function to the ankle, and there is moderate evidence that neuromuscular training can prevent future ankle sprains. There is strong evidence that bracing prevents ankle sprains; however, one study included in a meta-analysis made the effects of bracing nonsignificant. In general, ankle bracing is considered for recurrent sprains and is tolerable for most activities. Chronic instability can develop after acute ankle sprain in 10–20% of people and may require surgical stabilization.

When to Refer

- Ankle fractures.
- Recurrent ankle sprains or signs of chronic ligamentous ankle instability.
- No response after > 3 months of conservative treatment.

2. Eversion ("High") Ankle Sprains

ESSENTIALS OF DIAGNOSIS

- Severe and prolonged pain.
- Limited range of motion.
- Mild swelling.
- Difficulty with weight bearing.

General Considerations

A syndesmotic injury or "high ankle" sprain involves the anterior *tibio*fibular ligament in the anterolateral aspect of the ankle, superior to the anterior *talo*fibular ligament.

The injury mechanism often involves the foot being turned out or externally rotated and everted (eg, when being tackled). This injury is commonly missed or misdiagnosed as an ATF ligament sprain on initial visit.

Clinical Findings

A. Symptoms and Signs

Symptoms of a high ankle sprain include severe and prolonged pain over the anterior ankle at the anterior tibiofibular ligament, worse with weight bearing. This is often more painful than the typical ankle sprain. The point of maximal tenderness involves the anterior tibiofibular ligament, which is higher than the ATF ligament. It is also important to palpate the proximal fibula to rule out any proximal syndesmotic ligament injury and associated fracture known as a "Maisonneuve fracture." There is often some mild swelling in this area, with or without an ankle effusion. Range of motion is usually limited in all directions. To perform the **external rotation stress test**, the clinician fixes the tibia with one hand and grasps the foot in the other with the ankle in the neutral position. The ankle is then dorsiflexed and externally rotated, reproducing the patient's pain. (**Note:** The patient's foot should have an intact neurovascular examination before undertaking this test.)

B. Imaging

Radiographs of the ankle should include the AP, oblique (mortise), and lateral views. The mortise view may demonstrate loss of the normal overlap between the tibia and fibula, which should be at least 1–2 mm. Asymmetry in the joint space around the tibiotalar joint suggests disruption of the syndesmotic ligaments. If there is proximal tenderness in the lower leg especially around the fibula, an AP and lateral view of the tibia and fibula should be obtained to rule out a proximal fibula fracture. Radiographs during an external rotation stress test may visualize instability at the distal tibiofibular joint. MRI is the best method to visualize injury to the tibiofibular ligament and to assess status of the other ligaments and the articular cartilage.

Treatment

Whereas most ankle sprains are treated with early motion and weight bearing, treatment for a high ankle sprain should be conservative with a cast or walking boot with limited weight bearing for 4–6 weeks. Thereafter, protected weight bearing with crutches is recommended until the patient can walk pain-free. Physical therapy can start early to regain range of motion and maintain strength with limited weight bearing initially. Follow-up of athletes over 18 years showed that conservative treatment can be successful, although 27% of patients had radiographic signs of ankle arthritis, including some with heterotopic ossification.

When to Refer

If there is widening of the joint space and asymmetry at the tibiotalar joint, the patient should be referred urgently to a foot and ankle surgeon. Severe or prolonged persistent cases that do not heal may require internal fixation to avoid chronic instability at the tibiofibular joint.

HEALTH CARE FOR SEXUAL & GENDER MINORITY PATIENTS

Definitions & Concepts

Gender identity is a person's internal sense of gender, which is independent from the sex assigned at birth. Gender is also independent from **sexual orientation**, which refers to a person's sexuality and encompasses three dimensions: *identity, behavior,* and *desire*. The term **sexual and gender minority (SGM)** refers to a broad group including lesbian women and gay men, bisexual, pansexual, and queer people (**sexual minority [SM] people**), and transgender and gender nonbinary people (**gender minority [GM] people**)—also commonly referred to as "**LGBTQ**" or "**LGBTQ+**." The plus sign is inclusive of individuals of other identities such as asexual, genderqueer, and polysexual. People who are intersex—those with variations in sexual development—are sometimes included within SGM populations, but a discussion of their health and care needs is beyond the scope of this chapter.

Population estimates of SGM adults in the United States range from 4.5% to 7.6%, depending on definitions, and differ across generations in the setting of evolving societal acceptance and safety, with approximately 22% in Generation Z (born 1997–2012) openly identifying as part of the community compared with 1% of the Silent Generation (born 1945 or earlier). Reliable population estimates, however, are lacking because there are no consistently applied federal and other administrative survey methodologies.

Transgender people have a gender identity that differs from the sex that was assigned at birth, including those who identify as nonbinary and those who have a gender identity that is neither man nor woman. **Transmasculine** refers to those who have a male- or masculine-spectrum gender identity and were assigned female at birth, and **transfeminine** refers to those who have a female- or feminine-spectrum gender identity and were assigned male at birth. **Cisgender** refers to people whose gender identity and birth assigned sex are the same (ie, they are not transgender). *Transgender people may also be sexual minorities (ie, lesbian, gay, bisexual, etc) or straight/heterosexual.* For the sake of expediency in this chapter, the sections on SM men and women omit the term "cisgender"; however, readers should take into consideration that, for example, gay transmasculine persons may have vaginal receptive sex with cisgender men as sexual partners, and therefore should be screened for contraception needs, and cisgender lesbian women may have transfeminine partners who retain their penis.

Sexual identities include **gay** (those who are predominantly attracted to or sexually active with members of the same gender), **bisexual** (those who are attracted to or sexually active with people of more than one sex or gender), and **heterosexual** or **straight** (someone who is attracted to or sexually active with people of another gender [historically the "opposite" gender]); however, other terms may be used, and terminology changes over time. A growing number of people identify as **pansexual**, which describes an attraction to people of any gender—man, woman, or throughout the gender spectrum. The term "**queer**" has been reclaimed by many SGM people to represent someone with a sexual orientation, gender identity, or **gender expression** (the external manifestation of gender) that differs from that of a cisgender, heterosexual person. Because of the historical legacy of this term as derogatory, however, it should not be used unless someone specifies this as their identity. Studies have demonstrated that there is a broad diversity among those who identify as SGM and that many people have multiple gender identities or sexual orientations.

The three dimensions of sexual orientation—identity, behavior, and attraction—do not necessarily overlap. Health risk factors (eg, substance use) and outcomes have been found to be different among different dimensions. For example, one study found that gay and lesbian individuals with sexual identity-behavior discordance reported poorer psychological functioning and higher rates of alcohol binge drinking and suicidal ideation compared with those with identity-behavior concordance. *The incomplete overlap of identity and behavior means that clinicians cannot rely upon self-reported identity to infer sexual behavior, and vice versa*.

It is important to distinguish sexual orientation from gender identity. Knowing a person's gender identity does not identify their sexual orientation. Just as cisgender people may be sexually attracted to and have sex with people of any gender, so too can transmasculine, transfeminine, and nonbinary people have partners of any gender. *Routinely asking about sexual orientation, and when relevant for the clinical issue at hand, sexual behavior, helps build trust between the patient and clinician, ensures appropriate medical care (eg, appropriate screening tests for STIs and family planning), and contributes to better health outcomes.* To ensure that people feel welcomed, the clinician can ask people for their correct name and pronouns by first offering the clinician's correct name and pronouns. For example, the clinician may say "Hello, I'm Dr. (insert name). I use they/them pronouns. What name and pronouns would you like me to use for you?" Pronouns can also be included on ID badges and email signatures. To inquire about gender identity and sex assigned at birth, the following questions are recommended: "What is your current gender identity?" and "What sex were you assigned at birth?" *The clinician needs to remember that name and pronouns may differ from what one thinks may "match" people's gender identity, sex assigned at birth, or gender expression, or what is on "official" documentation, but the clinician must always use the name and pronouns that people share.*

Sexual orientation and gender identity may change over time or be situational (eg, during incarceration, in educational settings). People may also hide their sexual orientation and gender identity from others, including clinicians, to avoid stigma and discrimination. Revealing a person's sexual orientation, gender identity, or both is called "coming out." This process may occur at any point in life and may vary by context (eg, being "out" to family but not to coworkers). *The binary concept of gender (that there are only girls and women or boys and men) is not evidence-based.* Some legal policies are moving to reflect this fluidity. In the United States, fewer than half of the states have three genders on legal documents: female, male, or nonbinary (neither male nor female), and the legal environment nationally is changing. These experiences and policies have implications for health screening for patients who receive care in health systems with pop-up reminders for sex-specific screening examinations such as mammography or prostate examinations.

Health Disparities & The Minority Stress Model

Providing compassionate and informed health care for SGM people involves acknowledging and addressing the negative effects of discrimination and stigma. The theory of minority stress and resilience, first published by Virginia Brooks in 1981 and later expanded by Ilan Meyer, proposes that *SGM individuals experience chronic, additive, and unique stresses that stem from living in discriminatory social conditions*; stressors include experiences of prejudice, expectations of rejection, the cognitive burden of deciding whether to come out in different circumstances, and internalized homophobia or transphobia.

SGM people also experience multiple social and structural barriers to equitable health. They are underserved by the medical community and understudied in medical research, with worse health outcomes compared with heterosexual and cisgender populations. These experiences also differ in those with other marginalized identities ("*intersectionality*"); SGM people of color and those with disabilities, for example, face even greater health disparities. A previous negative experience in a clinician's office may influence whether the patient will return even for an acute medical event, which can delay care and result in advanced disease. One in three transgender people report delays in seeking care due to prior discrimination, and one in five report being refused medical care due to their transgender identity. SGM adults are twice as likely to delay care than non-SGM adults. Other structural barriers include limited access to the health care system due to financial issues, lack of federal anti-discrimination protection, and increasing legislation restricting access to gender-affirming health care, at times compounded by multiple marginalized identities. SGM people have higher rates of poverty, lower rates of home ownership, and higher rates of homelessness than non-SGM people. These structural issues will take time to change. However, clinicians can impact the health outcomes of SGM people by ensuring that the clinical space is welcoming to people of all genders and sexual orientations (see below), obtaining comprehensive data on sexual orientation and gender identity, and being aware of the specific health needs of SGM people to advance the health of SGM patients. A study from Norway found that affirming environments can counteract minority stress and support overall health. There are significant numbers of SGM refugees from the increasing number of countries with anti-LGBTQ+ laws and policies, and clinicians need to be prepared to meet their health and legal needs with appropriate care and referrals.

The vast majority of SGM patients would like to come out to their clinician. Many clinicians, however, are concerned that their patients would be offended if asked about sexual orientation and gender identity. It is important that clinicians overcome any discomfort and ask appropriate questions of their patients. There are useful video resources to help clinicians with these issues; one example is the "Acknowledging Sex and Gender" online training video from the University of California San Francisco Center of Excellence for Transgender Health, available at https://prevention.ucsf.edu/transhealth/education/acknowledging-gender-sex. Specific populations have additional barriers to disclosure and thus shared decision making, such as those who speak languages other than English; a study of Latino and Latina SGM patients and their clinicians found significant diversity among individuals and emphasized that providers need to be aware of patients' varying social support from family members and that professional interpreter services should be SGM competent. A study from South Africa found that discriminatory and prejudicial attitudes by health care providers, combined with their lack of competency and knowledge, are key reasons for SGM health disparities. A 2024 study highlights the medical system's history of cruelty toward sexual and gender minorities in the United States—including the publication's own role—which helps explain why many SGM individuals are reluctant to seek medical care in the United States.

The number of adverse childhood experiences has been shown to be a predictor of future negative health outcomes. SGM individuals have higher adverse childhood experience scores than non-SGM individuals (18–60% versus 14% with four or more adverse childhood experiences). A study of transgender persons found that adverse childhood experiences were responsible for 18% of mental health variances. Additionally, the effect of neglect from being physically excluded from the family home due to sexual orientation or gender identity is a common experience that was not measured; many SGM youth are excluded from their home once they come out. A negative reaction of parents to their child's coming out is strongly associated with that child's future lack of housing, depression, and substance use.

SARS-CoV-2 had a disproportionate effect on the SGM community. SGM persons were more likely to be employed in workplaces highly impacted by the pandemic including food service, hospitals, education, and retail. One study found increased depression and anxiety coincident with the pandemic within the SGM community in persons who did not have preexisting anxiety or depression. Another study of young Swiss men found higher levels of psychological trauma, fear, isolation, and depression in SM men due to the pandemic. SGM adults were more likely to be laid off or furloughed from jobs during the early pandemic compared with non-SGM adults. SGM adults were also more likely to report difficulty affording household needs and rent or mortgage payments. A cross-sectional study of transgender individuals found higher odds of COVID-related medical care interruptions and housing instability compared with cisgender populations. A greater proportion of gay and lesbian adults (85%) reported receiving at least one dose of a COVID-19 vaccine compared with heterosexual and bisexual adults (76%). However, COVID-19 vaccination rates differed by race and ethnicity; vaccination rates were lowest among Black LGBT individuals, particularly women. SGM people were more likely to experience long COVID and to have activity limitations from long COVID.

Making Clinical Environments Welcoming to All SGM Patients

Part of serving SGM patients is to create a welcoming clinical space where each person is cared for and respected for all of who they are—including their sexual orientation, gender identity, and gender expression while considering other key aspects of their identities and lived experiences, such as race and ethnicity, age, educational level, geography and geo-political context, ability, and primary language. The use of people's correct names and pronouns throughout encounters is critical (see above). Implementation of comprehensive care, including acknowledging, respecting, and specifying care as needed for someone based on their sexual orientation, gender identity, gender expression, and correct names and pronouns, necessitates system change in many clinical settings. This includes making sure that (1) senior leadership is involved; (2) nondiscrimination policies are in place, are followed, and are prominently displayed; (3) open visitation policies are concordant with patients' choice of visitors; (4) outreach and engagement efforts are made for SGM patients; (5) staff receive culturally affirming training in the care of SGM people; (6) processes, forms, artwork, and reading materials reflect the diversity of SGM people; (7) data are collected about both sexual orientation and gender identity (including names and pronouns) in an open and nonjudgmental manner; (8) patients are routinely asked about their sexual health histories; (9) clinical care and services include prevention and wellness care with available family planning services and behavioral health services; (10) SGM staff are recruited and trained; (11) preventive care is concordant with clinical practice guidelines, where applicable; and (12) if all gender bathrooms are not available, a posting states that patients are welcome to use either the women's or men's bathroom and the patient can determine which bathroom to use. One exercise is to look at clinic materials (ie, signs, posters, brochures, magazines, intake forms, etc) and see if materials presume heterosexual behavior (*heteronormative*) and gender conformity (*cisnormative*). Often, materials discussing anatomy, sex, family planning, conception, pregnancy, and birth presume that everyone is cisgender, White, and primarily English-speaking. If so, find or create more broadly inclusive materials to replace them.

National LGBTQIA+ Health Education Center. https://www.lgbtqiahealtheducation.org. Accessed February 14, 2025.

Obtaining Sexual History from SGM Patients

The core history and physical examination are not different for SGM people in comparison to other patients. Clinicians should approach each patient as an individual, using patients' correct pronouns and appropriate terminology, respecting the diversity of gender identity as well as the differing desires for gender-affirming treatments, and performing an appropriate physical examination for the clinical encounter. When relevant, anatomic changes from any prior gender-affirming treatment should be noted. As with all adolescent or adult patients, a complete medical history should include a comprehensive sexual history. Clinicians may wish to preface discussion of the patient's sexual history with a statement indicating that this information is confidential. The Fenway Institute, which specializes in SGM health and health care, proposes using the following statement and follow-up questions: *"I am going to ask you some questions about your sexual health and sexuality that I ask all my patients. The answers to these questions are important for me to know how to help keep you healthy. Like the rest of this visit, this information is strictly confidential unless you tell me you are planning to harm yourself or someone else or describe someone else harming you."* Evidence suggests that most individuals are ready and willing to disclose to sensitive providers who make it clear the intent behind their questions. Additional questions are included in Table 47–1.

Rather than considering this a one-time intervention, it should be thought of as a process that is assessed over time and at critical junctures and changes in health status. However, *patients should not be expected to discuss their gender identity or transition in detail unless it is relevant to the current visit*. In addition, it is crucial that clinicians understand that transgender patients may have physical appearances (gender expression), names, and pronouns that are not reflected in their legal names or sex marker, as listed on identity documents. Staff members must learn how to elicit patients' names and correct pronouns so that these can be used consistently.

Key data to gather in a relevant sexual history include sexual function and satisfaction; number of partners if the patient is sexually active; the gender(s) of the patient's sexual partner(s); and the potential to conceive an unplanned pregnancy with the sexual partner(s). It should be noted that "sex" means different things to different people. Therefore, clinicians should determine the types of sexual practices the patient engages in (eg, oral sex, penile insertive anal sex, receptive anal sex, penis-in-vagina sex, fingers-in-anus sex) acknowledging these may not line up with clinicians' assumptions based on a person's sexual orientation. Additional key questions include how often condoms are used, if at all, for the different sexual practices the patient engages in; and whether drugs or alcohol, or both, are consumed in conjunction with sex. Clinicians should also establish whether there is a history of STIs because a positive history may have implications for medical follow-up and sexual risk assessment (eg, frequency of screening, syphilis serologies, chlamydia and gonorrhea testing, and discussion about HIV preexposure prophylaxis [PrEP]). For example, a recent diagnosis of syphilis would indicate the need for rapid plasma reagin titer monitoring to ensure adequate treatment and would prompt consideration of PrEP due to the association of syphilis with HIV infection.

Table 47–1. Inclusive questions to elicit a comprehensive sexual history.

Do you have a partner or a spouse? or Are you currently in a relationship?
When was the last time you had sex?
What is/are the gender(s) of your sexual partner(s)?
What body parts of yours touch which body parts of your partners?
How many people have you had sex with during the last year?
Do you have any desires regarding sexual intimacy that you would like to discuss?

The Association of American Medical Colleges has created a series of online videos that highlight gender and sexual history taking (https://www.aamc.org/initiatives/diversity/450468/gender-and-sexual-history1.html and https://www.aamc.org/initiatives/diversity/450470/gender-and-sexual-history2.html).

The Electronic Health Record

Electronic health record (EHR) systems should include functionality for the recording of gender identity and sex assigned at birth as well as chosen name and pronouns. Chosen name and pronoun should be displayed in all banners, schedules, and other viewing screens. Transgender persons can be identified within the EHR that supports the data collection of gender as separate from sex assigned at birth, by identifying those individuals whose entries for gender identity and assigned sex differ. *Collecting both gender identity and sex assigned at birth data is critical to understanding the population of people in care within a health system and their health needs*, such as age-appropriate cancer screening and appropriate interpretation of laboratory values, which may differ from EHR-labeled normative values for those using gender-affirming hormones.

Assessment and documentation in the EHR of a patient's sexual orientation and gender identity have been advocated in the United States by the National Academy of Medicine, the Joint Commission, and the Health Resources and Services Administration as fundamental to improving access to and quality of care for SGM people. However, there are risks for SGM people with having their sexual orientation and gender identity documented in the EHR. Examples of such risks include housing, child custody, and adoption discrimination. In 2020, the US Supreme Court determined that being fired on the basis of sexual orientation or transgender identity violated Title VII prohibition of discrimination on the basis of sex; however, there are still no federal protections against discrimination in housing, education, loans, or many other services. Further, same-sex relations are criminalized in multiple countries. Gender identity is likewise insufficiently protected. Therefore, *although sexual orientation and gender identity are critical to caring for the whole person, discussing with patients before documenting in the EHR is a best practice.*

Much work remains to be done in many other areas in the electronic health area, such as the family history template, which needs to be more inclusive for adopted people, gamete donors, and gender of parents.

Family Planning

A. Pregnancy Prevention

Comprehensive family planning for SGM people is important to address, so that all people can decide if, when, and how to build a family. Since a person's sexual orientation and gender identity do not determine sexual partners, all individuals should be asked about family-building intentions as well as contraception if pregnancy is undesired and their sexual activities that confer the possibility of pregnancy.

Most lesbian women have been sexually active with men at some point in their lives (85–90%), and 30% of self-identified adult lesbians are currently sexually active with men as well as with women. Compared with young heterosexual women, fewer lesbian and bisexual youth use highly reliable contraception. On multiple surveys, one of the reasons that lesbians do not access gynecologic care is the assumption by clinicians that they are heterosexual, and the (insensitive) advocacy of birth control in that assumptive atmosphere about their sexuality (ie, heteronormative). On the other hand, multiple studies show that the *unintended pregnancy rate of self-identified lesbian and bisexual youth is higher than that of the comparison heterosexual female youth*. Lesbian and bisexual female adolescents are also more likely than their straight peers to have engaged in sexual activity, have sex with cisgender boys at an earlier age, have had more frequent sex, and use a less effective contraceptive method.

Unintended pregnancy risk continues into adulthood with one sample reporting 24% of SM women having had unintended pregnancies. SM women also suffer higher rates of sexual assault compared with straight women. If a patient who self-identifies as a lesbian is having (penis-in-vagina) sex with men, one suggested question might be, *"Are you planning to get pregnant this year?"* If the answer is no, this is an opportunity to explain that studies show a higher unintended rate of pregnancy in lesbian women and to review effective contraception options. It is also a good time to talk about protection from STIs when having sex with a partner with a penis (ie, discuss condoms). *As with any person engaging in penis-in-vagina sex, experts recommend contraceptives in addition to condoms.* Condoms are only 80% reliable in preventing pregnancy with typical use; the addition of contraceptive vaginal foam or film can increase the effectiveness to almost 100%. Long-acting reversible contraceptives are especially important to consider. Long-acting reversible contraceptives such as a subdermal implant in the arm (0.05% annual failure) or either the copper or levonorgestrel IUDs are highly effective. The use of emergency hormonal contraception should also be considered and can be prescribed to have at home. Levonorgestrel, a one-step emergency contraceptive tablet, is available over-the-counter and can be used within 72 hours of unprotected intercourse.

Importantly, *patients should be counseled that gender-affirming hormone therapy is not a reliable contraceptive method*. Anyone with a vagina, uterus, ovaries, and fallopian tubes can potentially become pregnant if they engage in penis-in-vagina sex. Transfeminine persons and nonbinary individuals who have a penis and testes may still produce sperm capable of fertilizing an oocyte even if using gender-affirming estrogen, testosterone blockers, or both. Transmasculine persons and nonbinary individuals who have a uterus and ovaries can become pregnant, even in the setting of testosterone-induced amenorrhea. *All patients capable of pregnancy should be counseled on the importance of contraceptive use if they do not desire pregnancy.* Any of the contraceptive methods available to cisgender people are appropriate for use by transgender people and those using gender-affirming hormone therapy. Little is known about the contraceptive preferences of transgender people and clinical recommendations rely on expert opinion. Since testosterone can be a teratogen, patients who become pregnant while using this therapy should be referred early in pregnancy to a specialist such as a maternal-fetal medicine specialist, genetic counselor, or a clinician experienced in counseling patients about the risk of fetal exposure to exogenous hormones. There is also a national service (https://mothertobaby.org/) featuring current information on medications while pregnant or lactating.

The frequency of accessing abortion is the same between SGM persons and cisgender, straight persons. Termination of pregnancy can be considered in some situations or locations. Clinicians should be aware of abortion laws in the jurisdiction in which they practice. A 2021 study evaluated pregnancy termination for transgender, nonbinary, and gender-expansive people and found that most preferred medication abortion, due to their belief that it was the least invasive, although most respondents had undergone a surgical abortion. Respondents most frequently recommended that clinics that provide abortions and other services adopt gender-neutral or gender-affirming intake forms, that providers use gender-neutral language, and that greater privacy be incorporated into the clinic.

Moseson H et al. Abortion experiences and preferences of transgender, nonbinary, and gender-expansive people in the United States. Am J Obstet Gynecol. 2021;224:376.e1. [PMID: 32986990]

B. Family Building

Family building should be discussed with all patients, regardless of sexual orientation or gender identity. Options include foster-parenting or adoption (in some locations these options are not open to SGM persons), co-parenting a partner's child or children, becoming pregnant, contracting with a surrogate, or step-parenting. Some fertility practices refuse to assist SGM people with conception even if it is legal. In 2021, the American College of Obstetricians and Gynecologists reaffirmed Committee Opinion No. 749, stating, "No matter how a child comes into a family, all children and parents deserve equitable protections and access to available resources to maximize the health of that family unit." *All clinicians* "should recognize the diversity in parenting desires that exists in the lesbian, gay, bisexual, transgender, queer, intersex, asexual and gender nonconforming communities and should take steps to ensure that clinical spaces are affirming and open to all parties, such that equitable and comprehensive, reproductive health care can meet the needs of these communities."*

Eighteen percent of SGM people are parents to children under 18, including 35% of married LGBTQ adults. Approximately 5 million children in the US are being raised by an LGBT parent. At some point in their lifetime, 32% of LGB people and 19% of transgender people report having a child.

There are many paths to family building, and each is dependent on personal desires, reproductive capacity of the person and those of a partner(s) if any; any biologic/medical constraints; and legal/political options. Many options exist for conception and clinicians should be prepared to counsel patients, provide resources and refer as appropriate. Patients may decide to have inseminations with an unknown donor from a sperm bank (some unknown donors sign a release so that the child may contact the donor when the child reaches 18 years old), and some may decide to involve a known sperm donor. Most sperm banks are regulated regarding the administration of medical history forms, testing for STIs, and genetic screening. Known donors may have risk factors but are not routinely screened. It is important for future parents to be as informed as they can be about the legal implications of each option. In some states and countries, unless the insemination with known donor sperm takes place in the office of a physician, the known donor has full legal rights as well as financial responsibilities for the offspring. In one study of 129 lesbian mothers with 77 index offspring, 77.5% of the mothers were satisfied with the type of donor chosen (36% had chosen known sperm donors, 25% open-identity donors, and 39% unknown donors). Donor access and custody concerns were the primary themes mentioned by lesbian mothers regarding their (dis)satisfaction with the type of sperm donor they had selected. Donor siblings are often connecting through sites like "23 and Me" and often choosing to meet in person as adults.

Some lesbian women and couples in whom both partners have a uterus and ovaries decide to do "*co–in vitro fertilization (IVF)*," which is also known as "*reciprocal IVF*" in which one partner provides an egg, it is fertilized in the laboratory with sperm of a known or unknown donor, and then the other partner carries the pregnancy. A report in 2021 demonstrated significantly better reproductive outcomes after reciprocal IVF, with a clinical pregnancy rate of 60% compared with 40% after autologous IVF, and live birth rate of 57.1% in reciprocal IVF versus 29.8% in autologous IVF.

Lactation for the non-gestational parent can sometimes be induced by using a protocol that stemmed originally from the experiences of adoptive mothers who were motivated to breastfeed. Compared with straight women, infants born to lesbian-identified women have a lower chance of being breastfed or, if lactation is initiated, less chance of being breastfed for the first 6 months. The prevalence of a positive score on the Edinburgh Postnatal Depression screen was 35.6% in one study in SM postpartum women; higher concealment motivation was associated with depression symptoms via poor family and partner support.

Many SGM people delay childbearing until later in life, with resultant issues of age-related infertility, increased pregnancy loss, and fetal chromosomal abnormalities, as well as chronic health conditions such as hypertension that can affect obstetrical outcomes. Pregnancy outcomes of bisexual and lesbian women compared with women who identify as straight include increased risk of miscarriage and stillbirth, as well as very preterm birth.

There have been many studies on the overall outcomes of children of lesbian women, all of which have been favorable when comparing their children to children raised by straight parents. A 2020 study using administrative data from the Netherlands found that children of same-sex parents performed better in both primary and secondary education compared with children of different-sex parents.

Biologic options for pregnancy for cisgender gay men or transfeminine persons include conceiving with someone who may or may not be interested in co-parenting with them, or contracting with a friend, relative, or surrogate to carry the pregnancy after the sperm and a donor egg are fertilized and placed in the uterus of the surrogate. For transgender people, there are other options based on the organs they currently have. Prior to initiation of any gender-affirming hormones or gender-affirming surgical procedures, *a consultation with either an obstetrician/gynecologist or a reproductive endocrinologist to discuss fertility preservation and future genetic offspring is encouraged*. Reproductive planning is often not a priority for a transitioning youth but may become a desire in the future and may also be a priority for potential grandparents. Options are limited for transgender youth who have not undergone endogenous puberty before either starting gender-affirming hormones (with estrogen or testosterone) or puberty blockers and then going directly to estrogen or testosterone. The only future fertility option is either testicular or ovarian tissue cryopreservation, which is considered experimental. For transfeminine persons and gender nonbinary individuals who were assigned male sex at birth and who have reached adulthood after endogenous puberty, sperm can be stored, ideally prior to the initiation of estrogen. Of note, though some transfeminine persons still produce sperm even after long-term estrogen exposure, it is recommended that sperm cryopreservation occur prior to hormone start because the effect on fertility is hard to quantify and coming off hormones often can be dysphoric. For transmasculine persons and nonbinary individuals who were female sex assigned at birth and have gone through endogenous puberty, the next steps in genetic parentage will be based on the desire to carry a pregnancy and whether they have started gender-affirming hormones. Options include penis-in-vagina sex, intravaginal insemination, intrauterine insemination, and egg cryopreservation for the individual, a partner, or surrogate to carry. If a hysterectomy is planned as part of gender affirmation, discussion of whether ovaries are left in place should occur in light of consideration of future genetic parentage as well as future hormone regulation versus the risk of future ovarian cancer. In one study in Australia, however, only 7% of transgender and nonbinary adults had undertaken fertility preservation yet 95% said that fertility preservation should be offered to all transgender and nonbinary people. Participants who viewed genetic relatedness as important were more likely to have undertaken fertility preservation. Perinatal care providers should also ensure that all components of perinatal care are welcoming to SGM people.

All SGM persons planning a pregnancy should be encouraged to consult with a family attorney prior to conception, and if partnered, the partner needs to be aware of their rights and responsibilities. The law in the United States and most other countries has *not* kept up with the variety of family constellations that are seen in SGM families.

HEALTH CARE FOR LESBIAN & BISEXUAL WOMEN

Cisgender lesbian and bisexual women are addressed together in this section since most medical literature does not delineate clearly enough between lesbian and bisexual cisgender women. The medical literature also does not sufficiently consider the intersection of sexual orientation and gender identity to evaluate the specific health needs and concerns of lesbian and bisexual women who are of gender-diverse experiences, nor is there sufficient research in the experiences of other SM women (ie, those who identify as pansexual, queer, asexual) to understand the current health needs of these individuals. In the United States, women in same-sex couples are less likely to have primary care providers, get non-urgent medical care when needed, see a specialist, and feel that doctors spent enough time with them. Health care access is even more restricted at the intersection of sexual orientation, gender, race, and ethnicity. A 2021 study of Black and Latino/a SM gender-expansive women found that barriers to accessing care were linked to income and discrimination by providers. This is true worldwide with variability depending on the local sociopolitical climate. In countries with more restrictive laws and policies, health disparities are likely greater. Limited clinician training likely exacerbates the lack of preparedness to care for SM women.

Health Disparities Affecting Lesbian & Bisexual Women

Health disparities exist across the life span for lesbian and bisexual women compared with straight women, with higher prevalence of childhood physical abuse in the home, childhood sexual abuse, substance use including alcohol and tobacco, chlamydial infection as teens and young adults, sexual assault, depression, disabilities, increased BMI, intimate partner violence, threats and violence outside the home, asthma, arthritis, migraine, back pain, dementia, and CVD. Sexual dysfunction for lesbian and bisexual women is seen less often but is understudied and likely assessed at rates lower than among straight women (see Sexual History section). Bisexual and lesbian women in the Nurses' Health Study II experienced earlier all-cause mortality compared with straight women.

As with other SGM individuals, aging and advanced care planning is of importance in lesbian and bisexual women. Studies of Irish SGM older adults reveal concerns about residential care outside of their own home as well as respect by health professionals; similarly, there are concerns about home services for lesbian and bisexual women in Canada, Taiwan, and the United States. Lesbian and bisexual women have fewer children compared with straight women. Therefore, *it is critical that health care providers identify health decision makers for all patients who may find support in "family of choice" rather than "family of origin."* This is especially important since same-sex/same-gender marriage is not legal in many countries and is still considered socially unacceptable in many areas of the United States. To avoid conflict during critical decision-making moments, the health decision maker needs to be identified on the medical record after a private conversation with the patient. In one survey, only about 50% of same-sex couples who desired their partner to be the health decision maker had appropriate forms, and even if married, advance directives should be completed given past visitation denials. Elder abuse screening also needs to be done, since the incidence is unknown in this population.

McKetta S et al. Disparities in mortality by sexual orientation in a large, prospective cohort of female nurses. JAMA. 2024;331:1638. [PMID: 38662342]

Wang Y et al. Long-term care planning and the influencing factors among sexual minority older women: a qualitative study. J Adv Nurs. 2024;80:526. [PMID: 37530449]

Cardiovascular Disease

The risk of CVD, including MI and stroke, may be higher in SM women compared with straight women; information on CVD outcomes is limited, however, with studies showing mixed results depending on methodology. Studies suggest that CVD risk is most influenced by psychosocial stress (ie, cumulative minority stress). In one study, lesbian and bisexual women were 14% older in vascular terms than their chronological age, which was 6% greater than straight women; the risk was not fully explained by excessive cigarette smoking or alcohol use. Data from the Behavioral Risk Factor Surveillance System (2014–2016) showed that SM women, compared with their heterosexual counterparts, had increased modifiable CVD risk factors of mental distress, current cigarette smoking, heavy drinking, and obesity. SM women may have a higher prevalence of hypertension compared with heterosexual counterparts. SMs, particularly bisexual women, were less likely than heterosexual peers to use statins for primary prevention but not secondary prevention, potentially highlighting a gap in access. Data from the Chicago Health and Life Experiences of Women study, the National Health Interview Survey, and the National Health and Nutrition Examination Survey found cardiometabolic risk factors (eg, hypertension, diabetes, and obesity) and CVD varied by sexual orientation and race/ethnicity highlighting the importance of intersectional assessments and interventions that account for sexual orientation, race, and ethnicity.

Caceres BA…Rosendale N et al. Differences in ideal cardiovascular health between sexual minority and heterosexual adults. JAMA Cardiology. 2023;8:335. [PMID: 36811854]

Rosendale N et al. Differences in cardiovascular health at the intersection of race, ethnicity, and sexual identity. JAMA Netw Open. 2024;7:e249060. [PMID: 38691360]

Nicotine Exposure

Nicotine exposure (eg, cigarette smoking, vaping) is more common among lesbian and bisexual women than in straight women, particularly SM women of color, bisexual women, and queer youth. While estimates vary, studies consistently show a higher prevalence in lesbian and bisexual women compared with straight women, including in lifetime smoking (48.1% versus 44.9% versus 33.7%), current smoking (26.3% versus 29.9% versus 15.2%), past-month daily smoking (16.2% versus 18.7% versus 10.3%) and nicotine dependence (13.1% versus 15.2% versus 8.2%). The tobacco industry's well-documented targeted marketing to SGM groups and the use of nicotine to cope with psychosocial stressors are contributing factors. Early initiation of nicotine use (before age 15) accounts for some of the disparities in adult rates. Rates of cigarette smoking, e-cigarette use, and hookah use in SM high school students are higher than straight peers, particularly for bisexual youth. Protective factors against nicotine use for young lesbian and bisexual women included connections with other SGM people and parental support.

Both traditional smoking cessation programs and targeted SGM programs are effective for SGM people, although research into SGM-specific interventions is limited. One qualitative study from Canada detailed eight themes important in a smoking intervention: (1) be LGBTQ+ specific; (2) be accessible in location, time, availability, and cost; (3) be inclusive, relatable, and highlight diversity; (4) incorporate LGBTQ+ peer support and counseling services; (5) integrate other activities beyond smoking; (6) be positive, motivational, uplifting, and empowering; (7) provide concrete coping mechanisms; and (8) integrate rewards and incentives. Other studies have corroborated that both SGM-specific (such as relation to coming out, different norms and acceptability of smoking among SGM communities, or SGM-related minority stress) and previously identified factors seen in other populations (such as self-efficacy around quitting) are important to support SGM people in quitting smoking. Attention should be paid to youth-specific interventions and to messaging about cigarette smoking warnings. Patients should be encouraged to check with community or online resources for smoking cessation programs and encourage participation in SGM-tailored programs, if available.

Ganz O et al. Cigarette smoking behaviors and nicotine dependence at the intersection of sexual identity and sex in the United States: findings from the National Survey on Drug Use and Health. Prev Med Report. 2024;38:102593. [PMID: 38283968]

Ruiz RA et al. Associations of sexual orientation-related minority military stressors with past-year cigarette use among lesbian, gay, and bisexual veterans. Nic Tob Res. 2024;26:852. [PMID: 37878537]

Substance Use

Substance use is higher in lesbian and bisexual women compared with straight women. This is especially well documented for cigarette smoking and alcohol use; however, it has been shown as well for use of sedatives, cannabis, hallucinogens, opiates, and stimulants. Substance use disparities begin in youth and worsened during the COVID-19 pandemic. As with other conditions, SM women of color are particularly impacted, and urban-rural disparities exist. The increased rate of substance use persists for bisexual women over the age of 25 years but decreases for lesbian women at that time. As with cigarette smoking, disparate substance use rates have been associated with psychosocial stressors (eg, discrimination, housing insecurity), adverse childhood experiences, and mental health. Results from the longitudinal Chicago Health and Life Experiences of Women study showed that anxiety was prospectively associated with alcohol use, as were higher levels of perceived SM stigma. Alcohol use was prospectively associated with depression, suggesting a complex, multi-directional relationship between substance use, minority stress, and mental health. Increased heavy episodic drinking of alcohol was noted in lesbian and bisexual women including Black and Latina women, underscoring the importance of identity-affirmative and accessible behavioral and mental health treatment.

Multiple interventions have been initiated to decrease alcohol and other substance use in lesbian and bisexual women, however more research is needed. A 2020 study showed that greater LGBT supportive factors in a community (eg, PRIDE events) correlate with lower lifetime odds of marijuana use and smoking for youth. Community connectedness is protective against alcohol use in SGM people of color. Training in SGM cultural sensitivity is essential for treatment providers, as is organization-level interventions to ensure SGM-affirming care environments. Another approach studied in the rural United States looked at training and deploying SGM peer-advocates to support mental health and substance use and "bridge the gap in culturally competent care." SM women, compared with straight women, with lifetime alcohol use disorders are at heightened risk for concomitant psychiatric and drug use disorders, underscoring the need for substance abuse programs to address concurrent mental health concerns.

Body Weight

Most studies suggest a higher prevalence of obesity and overweight in lesbians and bisexual women compared with straight women. SM women of color may experience higher rates of obesity compared with White SM women, although data are mixed. The reason for this difference is likely multifactorial and complex. Structural factors, such as poverty, are associated with obesity in SM women, as are psychosocial stressors such as discrimination and weight stigma. Obesity and overweight may start at a young age, and they may conceptualize weight differently than straight peers. Prevalence of eating disorders is also higher in lesbian and bisexual women, with mixed findings on diet quality. A 2023 meta-analysis found no difference in physical activity between SM women and straight women, although it did find moderate to high heterogeneity in measures across studies. Bullying has been associated with high levels of unhealthy weight control behavior in SM youth. Lifetime trauma exposure has been associated with obesity in SM women.

Despite the prevalence of obesity in SM women, there are few targeted intervention studies. Research has identified themes related to weight for lesbian and bisexual women. Findings from focus groups included (1) a preference for interventions focusing on promoting health and full life participation rather than on weight loss only, (2) cultural norms within the lesbian community that were accepting of larger body types, (3) an increased awareness in older age that the larger body size may exacerbate chronic health problems such as knee pain, and (4) the importance of social support and group structures in initiating and maintaining healthy behaviors. One study of 150 lesbian, bisexual, and queer women offered preliminary evidence that social support, resilience, and self-esteem help foster body appreciation, which might be protective against mental health concerns and disordered eating.

Sullivan K et al. Disparities in physical activity between sexual minority and heterosexual women: a systematic review and meta-analysis. Prev Med. 2023;175:107708. [PMID: 37726039]

Diabetes

There are limited studies examining diabetes and prediabetes in SM women and results are conflicting and vary by methodology. In the Nurse's Health Study II, lesbian and bisexual women had a 27% higher risk of developing type 2 diabetes than straight women; however, this association was mediated by BMI. Data from the Behavioral Risk Factor Surveillance System (2017–2019) found slightly higher prevalence of diabetes in SM adults compared with straight adults (12.5 versus 11.6); however, this difference varied by race or ethnicity. There were no differences in glycemic status scores in women by sexual identity using data from the 2007–2016 National Health Nutrition and Examination Survey. There are no intervention studies to reduce diabetes and prediabetes in SM women.

Pulmonary Disease

Pulmonary disease has not been rigorously studied in lesbian or bisexual women; most of the data come from studies of asthma, which generally find higher rates in SM women compared with heterosexual women. Older lesbian women have a higher prevalence of lifetime and current asthma, even when statistical models are used to correct for current and past cigarette smoking and obesity.

Other findings of mediators on pulmonary health may help elucidate possible causative factors of pulmonary health. For example, one study of SGM persons found an association between shorter duration of sleep and outcomes, such as COPD prevalence. Further research is needed in this field, particularly considering disparate rates of smoking in SM women that may predispose to pulmonary disease.

Sexually Transmitted Infections

STIs occur in lesbian and bisexual women, but little population-based data are available to delineate precise risks. *Asking about sexual behaviors in addition to sexual identity is key to identifying STI risk and advising appropriate testing*, since risk may vary by specific sexual practice (eg, digital-vaginal, vaginal-vaginal, digital-anal, oral-vaginal, oral-anal contact) and the specific pathogen. Often data are mixed and inconsistent with respect to whether sources speak to infection risk by identity group or behavior. Delineating behavior-based risk and identity-based risk are important for research, assessments, and interventions. The CDC has found that women who have sex with women (WSW is identity-based) have diverse sexual practices (sexual practices are behavior-based); the CDC also noted that use of barrier protection in examined studies (eg, use of gloves, dental dams) was ubiquitously low.

1. Sexual practices—It is important to ask lesbian and bisexual women about specific sexual practices, as some practices may carry a higher risk of STIs than others, although there has been little research on sexual practices and the risk of STIs in this population. Thus, inferences are drawn from heterosexual prevention of these infections. “Safer Sex Kits” have occasionally been distributed to WSW and women who have sex with women and men (WSWM) to decrease the risk of STIs, but intervention effectiveness has not been studied. Female latex condoms and latex gloves may provide better protection against infectious transmission from oral sex since latex has been studied as a barrier for prevention of HIV and other STIs.

2. Chlamydial infections—These infections were higher in 14- to 24-year-old women who reported same-sex behavior when attending family planning clinics in the US Pacific Northwest compared with women who reported exclusively heterosexual behavior. Possible explanations for this observation include differences in these groups’ use of reproductive health care services, infrequent use of barrier methods to prevent STI transmission with female partners, trends toward higher-risk behaviors, and different social network characteristics. Regardless of sexual orientation, the CDC recommends annual *Chlamydia trachomatis* (and *Neisseria gonorrhoeae*) screening from the age of first sexual activity to the age of 25 years for all women.

3. HIV infection—Exchange of blood should be avoided as much as possible, especially in HIV-discordant lesbian couples, since viral genotype analysis has confirmed that *HIV can be transmitted sexually between women*. The clinician should encourage both partners in new lesbian couples to have comprehensive STI and HIV screening prior to sexual contact and recommend barrier protection for 6 months until the couple is again screened to verify that their HIV status is still negative. If the couple is consistently monogamous and HIV and other STI testing are negative, barrier precautions do not need to be continued. However most lesbian and bisexual women may not follow this advice, since many feel they are at low risk for HIV, which may be correct. Some lesbian and bisexual women are sex workers or have had sexual relationships with high-risk male sexual partners (sometimes gay male friends) and are at increased risk for STIs. CDC guidelines recommend that all women should be tested once in their lifetime for HIV, with testing repeated according to risk factors. If a lesbian or bisexual woman is in a high-risk relationship for HIV transmission (sex work, gay male partner, female sexual partner with HIV), *they should be educated about PrEP for HIV prevention and prescribed the appropriate medication.*

4. Herpes simplex virus (HSV)—This virus can be transmitted sexually between women. The same precautions regarding the transmission of HSV should be provided to lesbian, bisexual, and heterosexual women; there should be no sexual contact during any prodromal symptoms that may precede a genital herpes outbreak or during the blister stage of the outbreak. Suppression of lesions can usually be accomplished with antiviral medications, such as acyclovir or valacyclovir, if the lesions are recurrent (see Chapter 6).

5. HPV—There is evidence of HPV transmission between female sexual partners. Certain strains of HPV are causally related to many precancerous and cancerous lesions, including cervical dysplasia and cervical cancer (see Chapter 21). Ten percent of lesbian women have never had sex with men, yet cervical dysplasia and cervical cancer develop in some of these women. *All people with a cervix need cervical cancer screening*, which may include Papanicolaou smears, high-risk HPV strain testing, or both, according to timetables and risk factors provided by professional society guidelines (see Chapter 21). The rate of HPV vaccination in Black lesbian women was very low in one study; the OR for HPV vaccination was 0.16 for Black lesbian women compared with White heterosexual women, and 0.35 for White lesbian women compared with White heterosexual women. Bisexual women are vaccinated more frequently than either lesbian or heterosexual women. However, the overall HPV vaccination rate is low in adult women regardless of sexual orientation, so improvement in all groups should be the goal. One study demonstrated that the effect of the 2010 Affordable Care Act did increase vaccination rates among lesbian, bisexual, and straight US women. Administration of the HPV vaccine is critical to the prevention of cervical cancer; the CDC recommends HPV vaccination for all persons through age 45 years, shared decision making is recommended. Papanicolaou testing or HPV testing, or both, should be performed regardless of sexual orientation, to detect cervical cancer. Home HPV testing kits are now available which hopefully will increase the testing and detection of cervical cancer. In a national probability sample of who underwent Papanicolaou testing, WSWM had the same odds of testing as WSM only, whereas women with lifetime female partners had lower odds of testing. Those who identified as bisexual also had lower odds of testing.

About 20–50% of lesbian women use sexual aids (eg, vibrators, dildos, or other sexual toys); these should not be shared with partners and should be cleaned after use. *HPV can remain on these sexual aids for up to 24 hours after use, even after standard cleaning.*

6. *Trichomonas vaginalis*—This can be transmitted easily between female sexual partners. One study of women attending an STI clinic in the United States noted that *T vaginalis* was the most common curable STI found in this population with a prevalence of 17% in WSW and 24% in WSWM.

7. Bacterial vaginosis and vulvovaginal candidiasis—These infections are common among women and, according to the CDC, even more common among WSW. It is unknown whether bacterial vaginosis can be transmitted between women. A study from Australia found a 27% prevalence of bacterial vaginosis in women and their female partners; risk factors for bacterial vaginosis were four or more lifetime female sexual partners, a female partner with bacterial vaginosis symptoms, and smoking at least 30 cigarettes weekly. Routine screening for bacterial vaginosis, however, is not recommended and testing should be based on symptoms. One approach for a WSW who has symptomatic bacterial vaginosis is to treat her and not her female sexual partners. If symptoms recur, her female sexual partners should be evaluated and treated with consideration of re-treating the index woman. This strategy may also be used for treatment of recurrent or hard to treat vulvovaginal candidiasis, which technically is not considered to be sexually transmitted, but anecdotally, improvement has occurred with treatment of the index patient and female partner.

Various strategies for making reproductive and sexual health clinics and providers more amenable to serving SGM people were studied by a group in the United States, but the findings (such as ensuring counseling involves inclusive safe sex discussions that are relevant to SGM people) have broad face validity and relevance for other regional and medical focus settings as well.

Cancer

Little is known about the incidence and prevalence of various cancers in lesbian and bisexual women, since sexual orientation has not been routinely included in cancer screening programs and cancer registries. However, some data suggest that SM women may be at a higher risk for cancer-related mortality than heterosexual counterparts. Investigators from the Women's Health Study compared SM veterans and civilians to their heterosexual counterparts and found that SM women veterans had a higher risk of cancer-specific mortality. The National Health Interview Survey found bisexual women over age 65 years were 7.6% more likely to have a cancer diagnosis than a heterosexual woman of the same age, but the difference was not seen between lesbian and heterosexual women; the survey also found that lesbian and bisexual women have higher prevalence of cancer risk factors, such as tobacco use, underscoring the need for vigilant screening. *Since lesbian and bisexual women have barriers to accessing health care and may not see a clinician regularly, any visit to a health care provider is an opportunity to check on cancer screening status* (eg, colonoscopy, mammography, cervical cancer screening). There is also recognition that upon receiving a cancer diagnosis, SGM people face challenges in receiving equitable care throughout the cancer care continuum and may experience cancer differently and have different needs during their care; heterosexual and SM cancer survivors in the UK reported receiving different care. One qualitative study with SGM breast cancer survivors underscored the challenges of disclosing sexual orientation during cancer care and the importance of provider recognition that varying social networks are critical to positive experiences of care provision. The 2017 American Society for Clinical Oncology position statement recommends five action steps to enhance SGM cancer care and reduce disparities: (1) patient education and support, (2) workforce development and diversity, (3) quality improvement strategies, (4) policy solutions, and (5) research strategies. All providers need to consider whether their prevention, screening, diagnostic, treatment, and palliative approaches will be equitably experienced by lesbian and bisexual women. The National Health Interview Survey from 2013–2018 showed differences in the quality of life for lesbian and bisexual women surviving cancer compared with heterosexual women; lesbian women reported higher odds of fair or poor self-rated health, COPD, and heart conditions. Bisexual women reported higher odds of severe psychological distress, heart conditions, and food insecurity than did heterosexual women. Bisexual women had lower odds of receiving a recent mammogram than did heterosexual women.

Hutchcraft ML et al. Differences in health-related quality of life and health behaviors among lesbian, bisexual, and heterosexual women surviving cancer from the 2013 to 2018 National Health Interview Survey. LGBT Health. 2021;8:68. [PMID: 33325783]

Webster R et al. How can we meet the support needs of LGBT cancer patients in oncology? A systematic review. Radiography (Lond). 2021;27:633. [PMID: 32800429]

A. Breast Cancer

The literature has been mixed on whether lesbian and bisexual women have a slight increased risk of breast cancer compared with heterosexual women. Lesbian women, however, do have an increased prevalence of *risk factors* predisposing to breast cancer, including nulliparity (and decreased breastfeeding), alcohol use, obesity, and cigarette smoking. Vulnerability to inadequate screening, the development of cancer, or delayed diagnosis may further correlate with certain experiences such as a masculine gender presentation and practices like chest binding, as one study in China found. The literature is also inconsistent regarding the rate of mammography screening in lesbian women; however, one study showed that bisexual women were less likely than heterosexual women and lesbian women to adhere to mammography screening guidelines. Lesbian and bisexual women who have breast cancer may not want reconstruction at the same rate as heterosexual women and often find that breast cancer support groups focus on issues for heterosexual women (such as attractiveness to a male partner). Resilience and recovery factors vary in some ways between heterosexual and SM women.

B. Cervical Cancer

Primary prevention of cervical cancer is essential. All persons between the ages of 9 and 45 years (routine recommended age is 11 to 12 years old) should receive the HPV vaccine series. HPV can be transmitted sexually between lesbian or heterosexual partners. Cervical cancer screening, with Papanicolaou smears, primary HPV testing, or both, should be part of lesbian and bisexual women's health care at the same intervals as for heterosexual women according to national and international guidelines. Lesbian and bisexual women, however, receive Papanicolaou smears at a lower rate than sexually active heterosexual women, in part because many of the Papanicolaou smears are often done in reproductive health clinics; lesbians who are not interested in becoming pregnant or avoiding pregnancy may not access these clinical sites. In addition, some lesbian patients as well as their health care providers mistakenly think that lesbian women do not need Papanicolaou smears. *All lesbian and bisexual women need cervical cancer screening starting at the age of 21 years, consistent with recommendations for cervical cancer screening for all women.* Cancer prevention and control strategies for SM women that target provider education and policy intervention are needed to improve SM women's relationships with their providers and increase cervical cancer screening rates.

C. Lung Cancer

Compared with heterosexual women, lesbian and bisexual women are likely to have a higher rate of lung cancer due to their increased rate of cigarette smoking. The incidence and prevalence of lung cancer, however, have not been determined in this SM population. Nonetheless, gay men and lesbian women with significant use of cigarettes are at increased risk for lung cancer and are underscreened for early lung cancer detection with the use of low-dose helical CT.

D. Endometrial and Ovarian Cancer

Endometrial and ovarian cancers are increased among those with nulliparity, which is more likely in SM women. Obesity, a known risk factor for both cancers, appears to be more prevalent among SM women. Conversely, the use of oral contraceptives, which is protective against the development of both of these cancers, is lower in lesbian women than in heterosexual women. Vigilance toward and education about presenting signs and symptoms (eg, postmenopausal bleeding, early satiety, unintended weight loss) are important to detect cancers as early as possible. Neither incidence nor prevalence of endometrial or ovarian cancer has been determined in this SM population. Lesbian women are less likely than heterosexual women to have had bilateral salpingectomies or bilateral tubal ligations for sterilization, procedures that decrease the risk for ovarian cancer, since about 70% of ovarian cancers start in the fallopian tubes.

Violence

Compared with heterosexual women, lesbian and bisexual women have higher exposures to violence throughout their lifetimes. Lifetime prevalence of sexual assault may be as high as 85%. A 2019 study concluded that sexual orientation clearly plays a role in victimization when they found that compared with heterosexual women, bisexual women had 3.7 times the odds of initial victimization and 7.3 times the odds of repeat victimization, and lesbian women had 3.2 times the odds of repeat victimization even after controlling for other sociodemographic factors. In a study of four countries in southern Africa, nearly one-third of lesbian and bisexual women experienced forced sex and assault including "corrective rape" by men as an attempt to change the women's sexual orientation. In a study from Brazil about experiences of violence against lesbian and bisexual women, the prevalence was 65%: psychological 40%, in the public environment 63%, practiced by men 73%, by strangers 66%, and repeatedly 82%. Narratives revealed experiences in the family environment (insults, threats of suicide or homicide, and false imprisonment), and in public (harassing, beatings, and rape).

The CDC reports that 61% of bisexual women and 44% of lesbian women experience rape, physical violence, and stalking by an intimate partner. These rates are higher than similar trauma in heterosexual women (35%). Additionally, approximately 20% of bisexual women compared with 10% of heterosexual women have been raped by an intimate partner in their lifetimes. The rate of stalking experienced by bisexual women is twice that of heterosexual women and a higher percentage of bisexual women report being afraid of an intimate partner. A study of US armed services veterans found that compared with heterosexual women veterans, lesbian, bisexual, and queer women veterans were twice as likely to report emotional mistreatment and physical intimate partner violence and three times as likely to report sexual intimate partner violence. Despite alarming rates for women of any identity, lesbian and bisexual women survivors of sexual assault and interpersonal violence may experience unique difficulties when seeking assistance. These problems include a limited understanding of interpersonal violence in the relationships of lesbian and bisexual women, stigma, and systemic inequities (such as shelters unwelcome to this population, perpetrating partners being allowed into the same shelters as the survivor of the domestic violence, "outing" someone as a psychological threat, and staff lacking cultural sensitivity and appropriate training in working with lesbian and bisexual women). Barriers to preventing SGM violence include stigma, systemic discrimination, and a lack of understanding of SGM intimate partner violence.

Lesbian women asylum applicants are frequently not granted asylum in the United States, despite being victims of severe violence in their home countries due to lesbian or bisexual orientation. When studied, there are three possible mechanisms of erasure of violence in these cases: ruling that the violence experienced was unextreme, finding that the applicants' accounts of violence were unsubstantiated, or arguing that the violence experienced was unrelated to the applicants' sexual orientation.

Unmark E et al. Untangling the relationship between internalized heterosexism and psychological intimate partner violence perpetration: a comparative study of lesbian and bisexual women in Turkey and Denmark. J Interpers Violence. 2022;37:NP14337. [PMID: 33876984]

Mental Health

Lesbians and bisexual women have an increased risk of depression. Recent evidence has emerged that there may be primary care provider bias against screening lesbian women as frequently as heterosexual women for depression. There is also evidence that psychotherapists may ask microaggressive questions when clients are lesbian or transgender women, underscoring that many therapists are not trained in SGM issues and may have heteronormative and cisnormative bias.

Many of the health disparities and health risks faced by lesbians and bisexual women, such as depression and cardiovascular risk, have been attributed to *minority stress.* Therefore, rather than identifying mental health problems as synonymous with a SM identity or stemming from inborn association with minority sexual orientation, *minority stress causes mental health challenges that stem from societal discrimination and stigma borne by individuals with minority identities (and behaviors).* An examination of lesbian and bisexual women veterans from the US Behavioral Risk Factor Surveillance System found that SM women veterans were three times more likely than heterosexual women to experience "mental distress." Mortality risk from suicide is also elevated among women with same-sex partners. In the US National Epidemiologic Survey on Alcohol and Related Conditions–III, bisexual women had greater rates of specific psychiatric disorders than lesbians or heterosexual women. Resilience factors that are protective for mental distress and poorer mental health among lesbian, gay, bisexual, queer, and questioning youth and adults in Israel included family support as well as other community-level factors, such as friends' support, SGM connectedness, and having a steady partner. *How parents react to an adolescent's coming out has a profound effect on their child's health outcomes.* For those adolescents whose parents were supportive, there was less homelessness, depression, substance use, and unprotected sex. Interventions for building resilience can be important in achieving a reduction in anxiety and depression. There is some evidence that online friends can serve as a buffer and social support, especially for SGM youth, although in-person social support appears to be more protective against victimization. However, social media can also be a place where SGM youth experience bullying.

As of September 2024, sexual orientation change efforts (reparative or conversion therapy) for minors are outlawed in 70 cities or counties and 20 states in the United States, Puerto Rico, and District of Columbia, as well as in 25 other countries (https://www.equaldex.com/issue/conversion-therapy), although these data in the United States are changing. In a study in South Korea, participants who had undergone sexual orientation change efforts showed a 1.44–2.35 times higher prevalence of suicidal ideation and suicidal attempts than those without such an experience. Significant associations with suicidal observations and suicide attempts were also observed between having received advice to consider undergoing this experience.

There is evidence that being in a legally recognized same-sex relationship, particularly in marriage, diminishes mental health differences between heterosexual and SGM persons. In contrast, psychiatric disorders increased among lesbian, gay, and bisexual persons who lived in states in the United States that enacted constitutional amendments to ban same-sex marriage compared with states that did not. Now that there has been 20 years of legal marriage for same-sex couples in the US, there are unambiguously positive results for improved mental health.

Mental health inequities among bisexual and lesbian women are well documented. Compared with heterosexual women, bisexual and lesbian women are more likely to report lifetime depressive disorders, with bisexual women often faring the worst on mental health outcome. Risk factors for depression, such as victimization in childhood and adulthood, are more prevalent among bisexual women. One Chicago Health and Life Experiences study (an 18-year, community-based longitudinal study of SM women's health) compared Black bisexual and Black lesbian women with White lesbian women. The study found reports of victimization were higher in Black bisexual and Black lesbian women, but the odds of depression were significantly lower than in White lesbian women.

Internalized homophobia was significantly associated with depressive symptoms in a study in South Korea of LGB people. Only 22% had "come out" to their mother, and 11% to their father. Since the early 2000s, suicide rates in South Korea are among the highest of the Organization for Economic Co-operation and Development nations. The conclusion was that mental health interventions were needed for LGB adults who have high levels of internalized homophobia, as well as greater efforts are needed to enact protective legislation for SM individuals in South Korea.

HEALTH CARE FOR GAY & BISEXUAL MEN

This section is devoted to the primary care of cisgender gay, bisexual, and other men who have sex with men (**MSM**) regardless of their sexual identity. *Most health-related research that focuses on MSM categorizes men based on their sexual behavior as MSM, rather than their self-reported identification as gay, bisexual, or other identities.* Although sexual identity is not always congruent with sexual behavior, identity is important to recognize to optimize health and health care, especially when there is a difference on the basis of sexual identity (for example, gay- versus bisexual-identified men).

Demographics

The size of the MSM population in the United States is not known with certainty due to variability in the definition of sexual orientation used in surveys and the possibility that some survey respondents do not disclose gay or bisexual orientations because of concerns about discrimination. Nevertheless, based on available data, it is estimated that at least 2.5% of American adult men identify as gay, and an additional 2.0% of men identify as bisexual. The prevalence of LGBT identification is higher among younger individuals, with approximately 21% of those born between 1997 and 2003 identifying as LGBT. The proportion of men who engage in sex with other men or experience sexual attraction to other men is estimated to be higher, with 7.3% and 6.2% of adult men reporting some same-sex attraction and sexual behavior, respectively, in one national survey.

Health Disparities

Gay, bisexual, and other MSM face health disparities stemming from the biologic aspects of their sexual behavior or from minority stress, or both. Because of these disparities, MSM have been identified as a priority population for health-related research and improvement in health care by both the National Academy of Medicine and the federal government's Healthy People 2030 initiative. These health disparities are exacerbated if MSM have experienced early life traumatic events, such as sexual abuse or familial rejection.

Office of Disease Prevention and Health Promotion (ODPHP). Healthy People 2030. Goal: improve the health, safety, and well-being of lesbian, gay, bisexual, and transgender people. https://health.gov/healthypeople/objectives-and-data/browse-objectives/lgbt. Accessed February 14, 2025.

A. HIV and Other STIs

1. HIV infections—*MSM account for approximately 71% of all new HIV infections in the United States,* despite representing a small proportion (< 10% by any metric) of the country's male population. The high burden of HIV infection among MSM stems in part from the efficient transmission of the virus through receptive anal intercourse, which confers a higher risk of HIV infection than other sexual activities, such as penile-vaginal and oral intercourse. Role versatility can also uniquely potentiate HIV spread among MSM, since the same person can acquire HIV via receptive intercourse and then transmit by engaging in insertive anal intercourse with partners without HIV. The origin of disparate HIV rates between MSM and other populations is not solely biologic in origin, however, as societal stigma and psychosocial problems also contribute to sexual risk behavior among MSM. *MSM of color face an increased risk of HIV;* the CDC estimates that in the United States in 2022, 34% of new HIV diagnoses occurred among Black MSM, and 36% were among Latino MSM. Racial and ethnic disparities in HIV infections among MSM are not because of differences in sexual behavior or substance use but rather such factors as lack of access to medical care, lower rates of recent HIV testing among non-White MSM, and assortative mixing (ie, being more likely to have sex with partners from one's own racial or ethnic group).

2. Syphilis and gonococcal infection—Beyond HIV, some STIs are more common among MSM. In 2023, approximately 33% of primary and secondary syphilis diagnoses occurred in MSM. Syphilis is associated with a high likelihood of subsequent HIV acquisition in MSM and may serve as a marker for individuals who could benefit from intensive HIV prevention efforts, such as PrEP. Increased cases of ocular syphilis, occasionally resulting in blindness, have been reported, with most cases occurring in MSM. The incidence of gonorrhea among MSM exceeds that among men who have sex with women (MSW). MSM also are more likely than MSW to be infected with antibiotic-resistant gonorrhea. Most gonococcal infections in MSM occur at extragenital sites (ie, the pharynx or the rectum) where they may be asymptomatic, underscoring the importance of eliciting a comprehensive sexual history, including an inventory of potential anatomic exposures, to provide optimal STI screening for MSM.

3. Viral hepatitis—MSM face increased risks of viral hepatitis. Outbreaks of hepatitis A infection have been documented in MSM, likely due to anal sexual contact, including oral-anal exposure ("rimming") as well as insertive and receptive practices. Likewise, hepatitis B is more common among MSM than the general population; approximately 20% of MSM have evidence of either current or prior infection with hepatitis B by age 30 years. *This highlights the importance of universal hepatitis A and B vaccination for young gay and bisexual men, preferably prior to the initiation of sexual contact.* Finally, hepatitis C infection has been identified as prevalent among MSM with HIV and some MSM without HIV; although hepatitis C is generally not efficiently transmitted via sexual contact, it is associated with condomless receptive anal sex, group sex, manual insertion of fingers into the rectum ("fisting"), and recent STIs, which make the rectal mucosa more susceptible to hepatitis C acquisition and transmission.

4. Other infections—HPV infection, which can cause anogenital warts, anal dysplasia, and anal cancer, is more common among MSM than MSW. A meta-analysis estimated the prevalence of the oncogenic HPV type 16 in the anal canal to be 35.4% among MSM with HIV and 12.5% among MSM without HIV. Correspondingly, anal cancer incidence is higher among MSM with HIV than in MSM without HIV.

Enteric infections may be sexually transmitted among MSM engaging in anal sexual contact, especially oral-anal sexual contact, and should be considered in the differential diagnosis of GI concerns. These infections include giardiasis, amebiasis, and shigellosis. In addition, *Shigella* infections are more likely to be antibiotic-resistant among MSM than among other individuals.

Clusters of meningococcal disease among MSM in the United States and Europe have also been reported, particularly those frequenting saunas and bathhouses, prompting some jurisdictions to recommend meningococcal vaccination for MSM. Intimate contact with multiple partners has been identified as a risk factor for infection in some of these outbreaks.

The global clade II mpox outbreak beginning in 2022 predominantly affected MSM, who represented > 90% of all affected individuals. Before this outbreak, mpox was primarily reported in central and western Africa, outside of sporadic travel-related cases in other regions. Mpox causes a typically self-limited illness with rash and often fever, malaise, and lymphadenopathy. In the 2022 outbreak, anogenital lesions were identified in most affected people, suggesting sexual spread of the infection. While most people with mpox recover without the need for hospitalization or antiviral treatment, people who are immunocompromised, particularly those with advanced and untreated HIV infection, are at risk for severe disease, including disseminated infection and death. The optimal treatment for people with or at risk for severe disease from mpox is not known, as RCTs of tecovirimat have not shown benefit. Vaccination with a non-replicating vaccinia virus vaccine (MVA-BN, also called JYNNEOS) reduces the likelihood of acquiring mpox and renders the infection less severe if it occurs despite vaccination. The mpox outbreak had diminished substantially by late 2022, likely due to a combination of safer sex and immunity from infection and vaccination. However, clade II mpox transmission continues. In addition, a multinational outbreak of clade I mpox centered in Africa was identified; only a single travel-related case had been confirmed in the United States by the end of 2024.

B. Behavioral Health

Likely due to minority stress (ie, growing up in non-affirming societies), MSM experience mental health disorders more commonly than other men. Whether defined by self-reported identity as gay or bisexual or behaviorally by report of sexual activity with other men, MSM have a higher lifetime prevalence of depression and anxiety disorders than men who identify as heterosexual or those who report sexual activity only with women. Behaviorally bisexual men experience a higher burden of both depression and anxiety disorders, compared with men who engage in only same-gender sexual behavior, in part because bisexual men may have less access to defined communities of choice, like self-identified gay men. The increased prevalence of mental health disorders among behaviorally bisexual men may also stem from dual stigmatization by both the straight and gay male communities, as well as internalized stigma. Among MSM overall, anti-gay violence, community alienation, and dissatisfaction with an idealized body image have all been associated with depression.

C. Substance Use

Compared with men who have only female sexual partners, MSM are more likely to report lifetime recreational drug use; they are specifically more likely to have used cocaine, hallucinogens, inhalants, analgesics, and tranquilizers. In addition, men who identify as gay or bisexual are more likely to smoke cigarettes than those who identify as straight. Although it is not clear that MSM are more likely than others to use methamphetamines, methamphetamine use in MSM communities has been linked to increased sexual risk behavior and transmission of hepatitis C, HIV, and other STIs. Consistent with the minority stress model, experiences of discrimination have been independently associated with substance use among MSM.

Blair CS et al. Examining the relative contributions of methamphetamine use, depression, and sexual risk behavior on rectal gonorrhea/chlamydia among a cohort of men who have sex with men in Los Angeles, California. Sex Transm Dis. 2022;49:216. [PMID: 34654768]

Preventive Care & Clinical Practice Guidelines

Clinicians can help address health disparities affecting MSM by following clinical practice guidelines that pertain to this population (Table 47–2). *The CDC recommends that sexually active MSM undergo screening for HIV, syphilis, gonorrhea, and chlamydia annually and more often if the sexual history warrants more frequent assessment*. An HIV antibody-antigen assay is preferred to HIV antibody alone for HIV screening because this test increases the sensitivity for detection of acute or recent HIV infection. Nucleic acid amplification testing (NAAT) provides optimal sensitivity for diagnosis of gonorrhea and chlamydia and can be performed on the oropharynx, rectum, urine, and urethra. MSM should be screened for these infections at any of the aforementioned sites that may have been exposed during sex, regardless of condom use. First-catch urine and urethral specimens for gonorrhea and chlamydia NAAT in men provide comparable accuracy to urethral swab; thus, there is no advantage to obtaining it for routine screening. Rectal and pharyngeal swabs for NAAT can be self-collected.

Table 47–2. Clinical practice guidelines pertaining to the care of men who have sex with men (MSM).

Recommendation	Comments
Immunizations	
HPV	Recommended up to age 26 years; the vaccine may be offered to those aged 27–45 years
Hepatitis A and B	Consider prevaccination serologic testing if the immunization history is uncertain; vaccinate if seronegative
Meningococcal	Recommended by some jurisdictions due to outbreaks of meningococcal disease among MSM
Mpox	Recommended for people with HIV and MSM who, in the prior 6 months, have been diagnosed with an STI or had more than one sex partner
Medications	
Preexposure prophylaxis for HIV	For MSM at high, ongoing risk of HIV infection (eg, anal sex without a condom, recent STI diagnosis, sexual partner with HIV)
Postexposure prophylaxis for HIV	Consists of 28 days of antiretroviral medication following a discrete exposure to HIV
Postexposure prophylaxis for STIs with doxycycline	Consists of a single 200 mg dose of doxycycline taken within 72 hours after condomless sex for MSM with a history of a bacterial STI in the past year
Screening Tests	
HIV serology	At least annually, more often if indicated by the sexual history
Syphilis serology	At least annually, more often if indicated by the sexual history
Nucleic acid amplification test for gonorrhea and chlamydia	At least annually, more often if indicated by the sexual history; all potentially exposed sites (oropharynx, urethra, rectum) should be screened
Hepatitis C serology	Annually for MSM with HIV and MSM without HIV engaging in behaviors that might expose them to blood (eg, injection drug use or traumatic anal sexual practices)
Anal cytology	For MSM with HIV beginning at 35 years and for MSM without HIV beginning at 45 years
Behavioral health (depression, substance use)	At the first clinical encounter, with follow-up screening for those who report behavioral health concerns

The CDC also recommends that MSM be screened for chronic hepatitis B infection at least once in their lives and that they be vaccinated against hepatitis A and B. Annual hepatitis C screening with a hepatitis C antibody test is recommended for MSM with HIV due to the elevated incidence of this infection in this population and the availability of well-tolerated, curative therapy. MSM without HIV who engage in sexual practices that may abrade the rectal mucosa (eg, group sex, fisting) may also benefit from annual hepatitis C screening.

The CDC, USPSTF, and the WHO recommend PrEP for HIV for MSM at high likelihood for HIV infection. FDA-approved options for MSM for PrEP include oral emtricitabine/tenofovir disoproxil fumarate, oral emtricitabine/tenofovir alafenamide, and long-acting injectable cabotegravir. Lenacapavir, an antiretroviral agent administered subcutaneously every 6 months, has also demonstrated efficacy for HIV prevention among MSM. Individuals with a high likelihood for HIV include those who engage in condomless anal sex outside of a monogamous relationship with a man without HIV; those who have a recent diagnosis of a bacterial STI; and those who have sexual partners with HIV who are not consistently virologically suppressed on antiretroviral therapy. PrEP has been shown in RCTs to prevent HIV infection in MSM and is addressed in more detail in Chapter 36. FDA-approved condoms can also decrease transmission of STIs during anal intercourse (One Male Condom); condomless anal intercourse carries the greatest sexual exposure risk of HIV transmission. These condoms can also be used to reduce the rate of pregnancy and the transmission of STIs during vaginal intercourse.

Clinicians who care for MSM should also be aware of antiretroviral postexposure prophylaxis (PEP) for HIV, which consists of antiretrovirals started within 72 hours of a discrete exposure to HIV and taken for 28 days, and either provide PEP themselves or be able to rapidly link patients to PEP care (see Chapter 36).

HPV immunization is recommended for all boys and young men up to age 26 years. For unvaccinated adults aged 27–45 years, shared decision making around HPV vaccination is recommended. *The HIV Medicine Association recommends routinely screening MSM with HIV for anal cancer and cancer precursors with anal cytology*; an RCT, the ANCHOR study, showed that screening for and removing anal cancer precursors significantly reduced the risk of anal cancer compared with screening and monitoring alone. Patients with abnormal anal cytology are typically referred for high-resolution anoscopy with biopsy. Colonoscopy performed for colon cancer screening is not considered a substitute for anal cytology or high-resolution anoscopy because colonoscopy does not assess for cellular abnormalities in the anal canal. Anal cytology, high-risk HPV testing, or both for screening of MSM without HIV is recommended in international consensus guidelines, beginning at age 45. If a screening test is negative, it should be repeated in 12–24 months depending upon the screening strategy used (cytology, high-risk HPV testing, or both).

Mpox vaccination with MVA-BN (JYNNEOS) is recommended for MSM who have had recent exposure to or who anticipate risk for mpox. This includes men with a recent diagnosis of an STI, those with more than one recent sex partner, those who have had sex at a commercial sex venue or large public event, and those who anticipate any of these behaviors in the future (https://www.cdc.gov/poxvirus/monkeypox/interim-considerations/overview.html).

Finally, clinicians should ensure that MSM are offered preventive care recommended for all individuals, including smoking cessation counseling and pharmacotherapy, screening for depression, and assessment for and counseling about alcohol misuse (see Lesbian and Bisexual Women's Health, above). Some studies have found that behavioral health programs tailored specifically for MSM are more effective in promoting healthy behaviors than those that are not culturally sensitive.

HEALTH CARE FOR TRANSGENDER & GENDER-DIVERSE PEOPLE

Terminology

This section addresses the unique health needs of transgender and gender-diverse persons. The terms **transgender** and **gender diverse** as used in this text are inclusive of those who identify with the terms **gender nonbinary**, **gender nonconforming**, **genderqueer**, and **transsexual**. The umbrella term "transgender" incorporates a range of identities and experiences of individuals whose gender identities or expression, or both, differ from those associated with the sex assigned to them at birth. In contrast, the gender of cisgender individuals is concordant with the sex assigned to them at birth. The term **transfeminine** as used in this text refers to persons who identify along a female or feminine spectrum and **transmasculine** refers to people who identify along a male or masculine spectrum. Despite this simplification, a significant proportion of transgender people do not identify with a binary conception of gender. Transgender people may use any pronoun, including the gender-neutral singular pronoun "they." It is also important to note that sexual orientation is distinct from gender and transgender people, like cisgender people, have a diversity of sexual attraction and activity.

Demographics

Few well-designed, long-term, large studies describe the population and well-being of transgender people. Additionally, methodological challenges exist in the description of the transgender population; these limitations include inconsistent or incomplete collection of sexual orientation and gender identity information in the medical record, population databases, and health studies, and variable case definition (self-identification, clinical diagnosis, or receipt of gender-affirming treatment). Survey-based studies that use self-identification report a prevalence of transgender and gender-diverse identities of 0.5–4.5% among adults and 2.5–8.4% among children and adolescents.

Herman J et al. How many adults and youth identify as transgender in the United States? The Williams Institute, UCLA School of Law. 2022. https://williamsinstitute.law.ucla.edu/publications/trans-adults-united-states/. Accessed September 4, 2024.

Disparities

Transgender people experience multiple structural barriers to health. High levels of societal stigma and discrimination, along with the lack of legal protections in education, the workplace, and housing, result in socioeconomic disadvantage and housing instability. Transgender people also face discrimination when seeking medical care. One in four transgender people reports delay in seeking medical care for fear of being mistreated based on their gender; among those who accessed a health care provider in the last year, 48% reported having a negative experience related to being transgender. These findings correlate with reports from health care professionals who state they lack the knowledge and skills necessary to provide care for transgender people.

James S et al. Early insights: a report of the 2022 US Transgender Survey. National Center for Transgender Equality. https://ustranssurvey.org/. Accessed September 4, 2024.

Gender-Affirming Medical & Surgical Interventions

Many, but not all, transgender people will seek gender-affirming medical or surgical treatments, or both, to align their physical appearance with their gender. Not all transgender people seek all interventions, and some may seek none; the standard of care is to provide transgender persons with adequate counseling and education on treatment options, expected outcomes, plan of care, and risks so that they can make an informed decision on which interventions they desire. When considering the risks of gender-affirming treatment, the clinician must also consider the significant risks of withholding such treatment on the well-being of transgender patients, including detrimental effects on mental health, increased suicidality, and increased substance use.

Gender-affirming treatments are recognized as medically necessary and essential services, shown to improve the well-being of transgender people in multiple psychosocial domains, including attendance at routine health maintenance. Gender-affirming care is delivered in diverse settings by health professionals of many disciplines and specialties. Many treatments, including hormone therapy, can be provided in an informed-consent model by appropriately trained specialty and primary care clinicians competent in making the diagnosis of gender incongruence. Mental health referral and treatment may be helpful for transgender people but is not a prerequisite for receiving gender-affirming treatments. Referral to experienced providers or a multidisciplinary team may often be appropriate.

Many gender-affirming treatments, including hormone therapy, impact the reproductive capacity of transgender people. Patients should be counseled on the reproductive implications of gender-affirming treatments along with options for family building and fertility preservation. *Gender-affirming hormone therapy is not a reliable form of contraception and all patients should be offered comprehensive family planning counseling.*

Guidance on the management of gender-affirming treatment is available from professional and specialty organizations along with publications from expert multidisciplinary clinics.

A. Feminizing Hormone Therapy

The goals of feminizing hormone therapy include breast development, reduction of body hair, reduced muscle mass, and redistribution of body fat similar to that of cisgender women. The general approach of therapy is to obtain physiologic premenopausal cisgender female range estrogen and testosterone levels through the combined use of an estrogen with an androgen blocker and, in some cases a progestin.

1. Estrogen—17-β-Estradiol is available in pill, patch, and injected formulation. The choice of route is based to some degree on patient preference (Table 47–3). Transdermal estradiol has a well-established safety profile based on studies in menopausal cisgender women. Injected estradiol is the least studied route and can be associated with both supratherapeutic levels as well as cyclical levels over the dosing interval. Estrogens should be continued after gonadectomy without reduction in dose. There is no direct evidence to guide decision making regarding the discontinuation of estrogen once a patient arrives at a menopausal age, though most experts believe initiating or continuing hormone therapy in transfeminine persons after age 50 is appropriate. Ethinyl-estradiol (found in hormonal contraceptives) and conjugated equine estrogens should *not* be used due to excess thrombogenicity.

The primary risk associated with estrogen therapy is VTE. The risk is minimal, however, when using 17-β-estradiol at physiologic estrogen dosing. Early studies showing 20- to 40-fold increased risk of VTE involved the use of ethinyl-estradiol at doses of up to 200 mcg daily and did not control for tobacco use. More recent studies found *no increased risk of VTE in transfeminine persons using transdermal 17-β-estradiol.* Thus, transdermal estradiol is the preferred route for those who use tobacco or with risk factors for or a personal history of VTE.

2. Anti-androgen—In the United States, the most commonly used anti-androgen is spironolactone, a potassium-sparing diuretic that is frequently used for female hirsutism or adult acne. Spironolactone inhibits both the synthesis of and action of testosterone. In higher doses (100–200 mg orally daily), spironolactone can lead to suppression of androgen levels into the female physiologic range. Common side effects include orthostasis and polyuria. Monitoring should include periodic assessment of kidney function and serum potassium. Other options for those who cannot tolerate spironolactone include a gonadotropin-releasing hormone (GnRH) analog, orchiectomy, or the use of a progestin. Finasteride and dutasteride (5-α-reductase inhibitors) are sometimes used as an alternative; however, they have limited effects. After gonadectomy, anti-androgens can be discontinued.

3. Progestins—Progestins may be an effective anti-androgen, particularly cyproterone acetate, which is used widely outside the United States as the primary androgen blocker in feminizing regimens. Although data are scant, some believe there is benefit to breast development, mood, sleep, and libido. In cisgender women, synthetic progestins have been associated with an excess thromboembolism and breast cancer risk. If used, micronized progesterone is recommended and should be initiated after at least several months of estrogen plus anti-androgen as to mirror breast development in cisgender women.

B. Masculinizing Hormone Therapy

The goals of masculinizing hormone therapy include facial and body hair growth, deepening of the voice, increased muscle mass, clitoral growth, induction of amenorrhea, and redistribution of body fat similar to that of cisgender men. The mainstay of therapy is administration of testosterone to achieve physiologic cisgender male serum testosterone level (Table 47–4). Blockade of estrogen is *not* needed; however, ovulation and menstrual suppression may be warranted to eliminate moliminal symptoms or in those with ongoing menses.

Testosterone is available as a topical gel, patch, injected formulation, and subcutaneous pellet. The use of daily

Table 47–3. Feminizing hormone therapy (listed in alphabetical order, within categories).

Hormone Therapy	Dosage			Comments
	Initial, low[1]	Initial, Typical	Maximum, Typical[2]	
Anti-androgen				
Dutasteride			0.5 mg orally daily	
Finasteride	1 mg orally daily		5 mg orally daily	
Spironolactone	25 mg orally daily	50 mg orally twice daily	200 mg orally twice daily	
Estrogen				
Estradiol cypionate, intramuscularly	< 2 mg every 2 weeks	2 mg every 2 weeks	5 mg every 2 weeks	May divide dose into weekly injections for cyclical symptoms.
Estradiol oral/sublingual	1 mg/day	2–4 mg/day	8 mg/day	If > 2 mg, dose should be divided and taken twice daily.
Estradiol transdermal	50 mcg	100 mcg	100–400 mcg	Maximum available single patch dose is 100 mcg. Frequency of change is brand and product dependent. Patients may find that > 2 patches at a time are cumbersome.
Estradiol valerate, intramuscularly[3]	< 20 mg every 2 weeks	20 mg every 2 weeks	40 mg every 2 weeks	May divide dose into weekly injections for cyclical symptoms.
Progestin				
Cyproterone acetate			10 mg orally daily	Used outside of the United States
Medroxyprogesterone acetate (Provera)	2.5 mg orally each night at bedtime		5–10 mg orally each night at bedtime	
Micronized progesterone	100 mg orally each night at bedtime		200 mg orally each night at bedtime	

[1] Initial low dosing for those who desire (or require due to medical history) a low dose or slow upward titration.

[2] Maximal effect does not necessarily require maximal dosing, as maximal doses do not necessarily represent a target or ideal dose. Dose increases should be based on patient response and monitored hormone levels.

[3] Available as standard US Pharmacopia (USP) as well as compounded products.

topical testosterone or using a weekly (versus biweekly) injection interval can help maintain even hormone levels in those with cyclical mood symptoms or pelvic cramping.

Prior concerns of testosterone-induced hepatotoxicity were based on the use of oral methyltestosterone. *There is no evidence to support a concern of hepatotoxicity in transmasculine persons using parenteral or topical testosterone.*

Common side effects of gender-affirming testosterone therapy include acne and male pattern baldness, both of which can be approached as in cisgender men. Hemoglobin and hematocrit should be monitored, and if the levels are elevated, consider reducing testosterone dose or changing to a transdermal form or weekly injections to maintain more even levels. It is important to use cisgender male reference ranges for hemoglobin and hematocrit due to the erythropoietic effects of testosterone and frequent oligo- or amenorrheic status of transmasculine people. Polycystic ovarian syndrome and obesity have been found to be at an increased prevalence in transmasculine persons prior to beginning testosterone therapy. Testosterone is not contraindicated in the presence of these conditions; instead, related metabolic disorders can be managed concurrently.

C. Monitoring Hormone Therapy

Hormone effects should be monitored both by clinical results as well as hormone levels, if available. *Patients should be reminded that results may vary and can take up to 5 years to reach maximal effect*; supraphysiologic hormone levels are not likely to enhance results but may incur excess risk. Note that reported laboratory reference range values may differ depending on the recorded sex of the patient; in general, clinicians should use the reference ranges driven by the current hormonal status of the patient. For example, female reference ranges will be included on automated laboratory reports of a transmasculine person taking testosterone if still registered as female. The interpreting clinician should use the male reference ranges for any tests run on this patient that have sexually dimorphic reference ranges. Tables 47–5 and 47–6 describe general monitoring

Table 47–4. Masculinizing hormone therapy (listed in alphabetical order).

Androgen	Dosage			Comments
	Initial, Low[1]	Initial, Typical	Maximum, Typical[2]	
Testosterone axillary gel 2%[3]	30 mg every morning	60–mg every morning	90–120 mg every morning	Comes in pump only; one pump = 30 mg
Testosterone cream[4]	10 mg	50 mg	100 mg	
Testosterone cypionate[5]	20 mg/week intramuscularly or subcutaneously	50 mg/week intramuscularly or subcutaneously	100 mg/week intramuscularly or subcutaneously	Double the dose for biweekly administration
Testosterone enthanate[5]	20 mg/week intramuscularly or subcutaneously	50 mg/week intramuscularly or subcutaneously	100 mg/week intramuscularly or subcutaneously	
Testosterone patch	1–2 mg every night	4 mg every night	8 mg every night	Patches come in 2-mg and 4-mg size. For lower doses, cut patch
Testosterone topical gel 1%	12.5–25 mg every morning	50 mg every morning	100 mg every morning	May come in pump or packet form
Testosterone topical gel 1.62%[3]	20.25 mg every morning	40.5–60.75 mg every morning	103.25 mg every morning	
Testosterone undecanoate[6]	N/A	750 mg intramuscularly, repeat in 4 weeks, then every 10 weeks	N/A	Requires participation in manufacturer-monitored program[6]

[1] Initial, low-dose regimen is recommended for genderqueer and nonbinary persons.

[2] Maximum dosing does not mean maximal effect. Furthermore, these dosage ranges do not necessarily represent a target or ideal dose. Dose increases or decreases should be based on patient response and monitored hormone levels.

[3] Doses < 20.25 mg with 1.62% gel or < 30 mg with 2% axillary gel may be difficult, since measuring one-half of a pump or packet can present a challenge. Patients requiring doses lower than 20.25 mg and whose insurance does not cover 1% gel may require prior authorization or an appeal.

[4] Testosterone creams are prepared by individual compounding pharmacies. Specific absorption and activity varies and consultation with the individual compounding pharmacist is recommended.

[5] Available as standard US Pharmacopia (USP) as well as compounded products.

[6] Testosterone undecanoate has been associated with rare cases of pulmonary oil microembolism and anaphylaxis; in the United States, the drug is available only through the AVEED Risk Evaluation and Mitigation Strategy (REMS) Program (https://www.aveedrems.com/AveedUI/rems/preHome.action). All injections must be administered in an office or hospital setting by a trained and registered health care provider and monitored for 30 minutes afterward for adverse reactions.

Table 47–5. Laboratory monitoring for feminizing hormone therapy (listed in alphabetical order).

	Comments	Baseline	3 Months[1]	6 Months[1]	12 Months[1]	Yearly	As needed

recommendations, rationales, and "sex-specific" laboratory values that may require individualized interpretation.

Cheung AS et al. Approach to interpreting common laboratory pathology tests in transgender individuals. J Clin Endocrinol Metab. 2021;106:893. [PMID: 32810277]

D. Surgical Interventions

Gender-affirming surgeries, including facial, chest, genital, and other procedures (Table 47–7) are available to transgender people. Outcomes evaluation of gender-affirming surgeries demonstrate high level of patient satisfaction, an increase in quality of life measures, and decrease in gender dysphoria. An increasing number of surgeries are being performed for gender affirmation; complication and regret rates are comparable to similar procedures performed for other indications.

Table 47–7. Gender-affirming procedures (listed in alphabetical order within categories).

Surgical interventions
- Augmentation mammoplasty
- Body contouring
- Chest surgery (augmentation/mastectomy, also referred to as "top surgery")
- Facial surgery (feminization/masculinization procedures)
- Gonadectomy (orchiectomy, oophorectomy)
- Hysterectomy, salpingectomy
- Phalloplasty, scrotoplasty, metoidioplasty, vaginectomy (including placement of penile/testicular prostheses)
- Thyrochondroplasty (tracheal cartilage shave/augmentation)
- Voice surgery
- Vulvoplasty, vaginoplasty

Other interventions
- Chest binding
- Facial and body hair removal (laser hair removal and electrolysis)
- Genital tucking and packing
- Hair implants
- Voice therapy and modification

Kloer C et al. Overview of gender affirming surgery for the gynecologic surgeon. J Gynecol Surg. 2021;37:269. http://doi.org/10.1089/gyn.2021.0042. Accessed September 4, 2024.

E. Long-Term Health Outcomes

The largest study of mortality among transgender people receiving gender-affirming hormone therapy is a 2011 Dutch cohort of 966 transfeminine persons and 365 transmasculine persons. Importantly, this study did not control for a number of risk factors, including tobacco use. All-cause as well as cardiovascular, cerebrovascular, and other disease-specific mortality among transmasculine persons did not differ from the general Dutch population of cisgender women. Among transfeminine persons, all-cause mortality was 51% higher than cisgender men in the general Dutch population, with the overwhelming majority of the difference due to HIV, drug overdose, and suicide; a 64% increased risk in cardiovascular mortality was seen; however, no significant difference was seen for cerebrovascular mortality.

Subsequent investigations, including those in European and United States cohorts, confirmed an increased risk of poor CVD outcomes among transgender and gender-diverse people. Data are conflicting on whether disparities in behavioral and social determinants of health contribute to poor cardiovascular outcomes. Transgender and gender-diverse people are more likely to experience health care and social discrimination, adverse childhood events, and psychological distress; the contribution of this excess minority stress to long-term health is unknown.

Poteat TC et al. Cardiovascular disease in a population-based sample of transgender and cisgender adults. Am J Prev Med. 2021;61:804. [PMID: 34364725]
Streed CG et al. Assessing and addressing cardiovascular health in people who are transgender and gender diverse: a scientific statement from the American Heart Association. Circulation. 2021;144:e136. [PMID: 34235936]

Cancer Risk & Screening

Several retrospective studies have not identified an increased risk of cancer in transgender people compared with assigned sex–matched controls. However, because of the numerous barriers to care as well as to identifying transgender people in clinical databases, underscreening and underreporting are likely. In general, an organ-based approach to screening should be taken, with attention to anatomic changes related to gender-affirming medical and surgical treatments. *There are no modifications to screening recommendations (or recommendations not to screen) for ovarian, uterine, or cervical cancer in transmasculine persons.* Breast cancer screening for transmasculine people who have not undergone mastectomy should be performed based on guidelines for cisgender women. The role of screening for breast cancer in transmasculine people who have undergone mastectomy is unknown and depends on the surgical technique used as well as technical limitations on screening small amounts of residual breast tissue. In transfeminine people, breast cancer screening using guidelines for cisgender women is recommended, with the modifications starting at age 50 years and only after a minimum of 5 years of lifetime estrogen exposure. Screening for prostate cancer in transfeminine people is complicated beyond the current debate over the utility of prostate cancer screening in cisgender men by the effects of feminizing hormones on prostatic hypertrophy and interpretation of tests of PSA.

Expert Panel on Breast Imaging; Brown A et al. ACR Appropriateness Criteria® transgender breast cancer screening. J Am Coll Radiol. 2021;18:S502. [PMID: 34794604]

Leone AG et al. Cancer in transgender and gender-diverse persons: a review. JAMA Oncol. 2023;9:556. [PMID: 36757703]

HIV

Disproportionately high rates of HIV infection among transgender people exist worldwide, and the largest burden of these infections is among transfeminine people and transgender people of color; the lack of targeted HIV prevention strategies for transgender communities may be one factor contributing to these disparities. Studies of pharmacologic PrEP, including daily oral medications and long-acting injectables, demonstrate acceptability and efficacy among transgender people; compared with cisgender MSM, however, adherence to PrEP was lower in transgender women and uptake and knowledge were lower among all transgender people. Disparities also exist in treatment of HIV, with transfeminine persons less likely to report receiving antiretroviral treatment and to remain in care. Modest interactions of unknown clinical significance may exist between antiretroviral medications and gender-affirming hormone therapy; clinical and laboratory response to therapy should be monitored. *Patients should be counseled that concurrent gender-affirming hormone therapy and antiretroviral therapy, including PrEP agents, is safe and effective.* Transgender people likely benefit from HIV prevention and treatment services integrated into other gender-affirming care.

SUBSTANCE USE DISORDERS (SUD)

ESSENTIALS OF DIAGNOSIS

- SUD are treatable, chronic health conditions that include periods of remission and activity.
- Not all non-prescribed substance use meets criteria for a SUD.
- SUD are characterized by ongoing use of substances despite harmful consequences and range from mild to severe *DSM-5* criteria.

General Considerations

SUD remain a significant public health issue in the United States, with widespread implications for individual and societal well-being. Excessive alcohol use remains a leading preventable cause of death in the United States, with 178,000 people dying from acute and chronic complications related to excessive drinking each year. With the increase in synthetic opioid use, the United States mortality rate related to opioid use has steadily climbed since 2010 and rose sharply during the COVID-19 pandemic. In 2021, opioid-related harms contributed to 108,000 deaths, roughly 1 in every 22 deaths, or about 3.1 million life years lost.

According to the 2022 National Survey on Drug Use and Health (NSDUH), approximately 57.8% of American adults aged 18 or older reported using alcohol in the past month, while 19.3% had used any illicit drug in the same period. The same survey reports 7.7% of adults met the criteria for an alcohol use disorder (AUD), and 3.6% adults had a diagnosable SUD involving illicit drugs.

Addiction is a chronic, primary condition of the brain that manifests as a compulsive drive to use a substance despite harmful consequences. Similar to other chronic diseases, such as hypertension or diabetes, addiction is influenced by genetics and the environment, with cycles of relapse and remission. The model of neural changes underlying addiction is a three-stage recurring cycle. It begins with binges and intoxication (mediated by the basal ganglia), progresses to a withdrawal state and dysphoria (mediated by the extended amygdala), and then reaches a state of preoccupation and anxiety if the substance is not used (mediated by the pre-frontal cortex). Substances that cause use disorders share the ability to release dopamine in the basal ganglia (ventral striatum), but over time, dopamine release diminishes, requiring greater use for the same effect (tolerance).

SUD is a treatable condition but not easily curable. Sustained treatment can result in recovery of brain function, normalization of brain biochemistry, and the resolution of problematic behaviors. *Early* remission is defined as abstaining from drug use for at least 3 months, while *sustained* remission is defined as abstaining for 12 months or more. For some people who use drugs of addiction, remission is the goal. For others, a harm reduction approach with reduced or safer use is the goal. Some individuals may not be ready to make changes to their use of drugs of addiction. The approach to addiction treatment should be patient-centered, multi-pronged, nonjudgmental, and unbiased, using non-stigmatizing language, and keeping the patient's goals at the forefront in order to continue patient engagement in healthcare.

Clinical Findings

A. Screening for SUD

The 2020 USPSTF statement recommends screening for unhealthy drug use among adults ≥ 18 years in primary care settings, including those who are pregnant or postpartum (Grade B). An expert panel of the Substance Abuse and Mental Health Services Administration (SAMHSA) similarly recommends primary care clinicians periodically and routinely screen all patients for SUD to reduce bias and preclude missed opportunities for intervention.

Screening, Brief Intervention, and Referral to Treatment (SBIRT) is a comprehensive, universal, public health approach to the delivery of early intervention for persons with risky drug and alcohol use, and timely referral to more intensive treatment for persons with SUD. The SBIRT model includes **S**creening to assess the severity of substance use, **B**rief **I**ntervention (5–10 minutes) focused on increasing insight and awareness regarding substance use and motivation toward behavior change, and **R**eferral to **T**reatment, where appropriate. For hazardous drug use or mild SUD, brief interventions are often appropriate. For moderate to severe SUD, referral for treatment is indicated.

There are multiple validated screening tools to assess for substance use:

1. **National Institute on Drug Abuse (NIDA) Quick screen** (eg, Single-Question Screener) is adapted from a single-question screen validated in primary care settings to efficiently screen for drug use. It asks: *"In the past year, how often have you used illegal drugs or prescription opioids for non-medical reasons?"* If a patient asks what "non-medical reasons" means, one can clarify this to be use "differently from how it's prescribed" or use "for the feeling or experience it causes." A response other than zero is considered a positive screen that should be followed by identification of the substance(s) used and a more complete assessment through an in-depth history.
2. **NIDA TAPS** is a more comprehensive screening tool for SUD or risky substance use. This 4-item screening questionnaire asks about the use of tobacco, alcohol, prescription medications, and other substances in the past 12 months. This tool is validated in primary care settings for patients to self-administer or complete with interviewers (https://cde.nida.nih.gov/instrument/29b23e2e-e266-f095-e050-bb89ad43472f).
3. **CRAFFT** is a validated screening tool to identify substance use, risky use, and SUD among pregnant individuals and youths 12–21 years old. Its use is recommended by the American Academy of Pediatrics Bright Futures Guidelines for preventive care screenings and well-visits. A CRAFFT score of 2 or higher was found to be optimal in identifying substance-related problems. The screen starts by asking about the frequency of substance use in the past 12 months. This is followed by "Have you ever ridden in a car with someone (including yourself) who was 'high' or had been using alcohol or drugs?" "Do you ever use alcohol or drugs to relax, feel better about yourself, or fit in?" "Do you ever use alcohol or drugs while you are by yourself?" "Do you ever forget things you did while using alcohol or drugs?" "Do your family or friends ever tell you that you should cut down on your drinking or drug use?" "Have you ever gotten into trouble while you were using alcohol or drugs?" The CRAFFT screening questionnaire can be found at https://crafft.org/.

Screening should be nonjudgmental and prioritize patient privacy and trust to encourage honest responses and sustained engagement. Importantly, a positive result on a screening tool is not a diagnosis, but rather a gateway to further assessment, treatment, provision of harm reduction resources, and referral to evidence-based treatment options. Screening tools should be combined with other information, like toxicology testing, to provide a comprehensive assessment of a person's substance use risk. (See Urine Toxicology Testing, below.)

B. Diagnosis of SUD

The *DSM-5* criteria determine an SUD diagnosis and its severity. The diagnosis of SUD is made when at least 2 of the following 11 criteria are met over 12 months (Table 48–1). Notably, the *DSM-5* recognizes *tolerance* and *dependence* as natural physiologic adaptations for any person with consistent exposure to substances. Therefore, tolerance and dependence alone in patients on prescribed long-term opioids who are taking their medication as directed do not satisfy the criteria for OUD. The 4Cs of addiction is a mnemonic to simplify recall of *DSM-5* criteria.

C. Urine Toxicology Testing

Toxicology testing is frequently used to augment the patient's self-report of disease activity by detecting and measuring substances used. The purpose of testing is to guide diagnosis and treatment and verify use of prescribed medications for SUD such as buprenorphine, a medication for opioid use disorder (MOUD). There is no clear evidence of benefit to routine toxicology testing when results will not change the treatment plan; rather, there may be potential harm in using testing for punitive reasons (such as dismissal from care).

Urine testing should involve patient informed consent unless the scenario is emergent and urine toxicology results will influence treatment, such as in evaluation of altered mental status or when the patient does not have capacity. Urine test results can have particularly significant implications in pregnant patients due to Child Protective Services involvement or management, and, as such, decisions to conduct testing should be taken only if results will meaningfully change care, and should be undertaken only after discussions with patients. Toxicology testing is available for various biologic samples including urine, oral fluid, hair, sweat, and meconium in newborns. The urine test is the preferred and most common source since it is easily collected, noninvasive, and has a wide variety of testing platforms available. Direct observation of urine sample collection is invasive and is not the standard of care. Urine is the only sample source currently approved for federally mandated testing for substances (biomarkers in hair and oral fluid are pending consensus standards).

There are two types of urine toxicology tests: immunoassay screens and liquid or gas chromatography with mass spectrometry. The specific substances identified, and threshold cutoffs for each test vary by laboratory or institution. Urine toxicology results are frequently mis-interpreted by clinicians; reviewing results with a toxicology or laboratory science specialist is recommended when results differ from those expected. Many commercially available assays do not test for novel substances such as xylazine or isotonitazene.

1. Immunoassay screens or ELISA—Antibody-based assays are typically performed quickly, cost less than spectrometry-based methods, allow for same-day results, and therefore are often used for initial point-of-care testing. The tests produce qualitative results, showing only whether a substance was identified as present or not. Tested

Table 48–1. *DSM-5* criteria for diagnosing substance use disorders.

Definition including Four Cs	*DSM-5* Criteria	Example Phrases to Ask Diagnostic Criteria
Craving	Strong desire or urge to use	Are there people, places, things, emotions, or other triggers that make you feel a strong urge to use X? Do you find yourself using your opioid medication to treat symptoms other than pain (eg, anxiety)?
Control (loss of)	Use in increased amounts or longer than intended	Have you found yourself using larger amounts of X, or for longer periods, than you thought you would? Have you ever run out of prescribed medication before a refill was due?
	Persistent wish or unsuccessful effort to cut down or control use	Have you tried to reduce or manage your use of X before?
	Much time spent to obtain, use, or recover from use	Have you found yourself spending more time on using or getting X to use than you used to? How do you spend a typical day?
Consequences	Failing to meet important obligations or fill roles	Has use of X made it more challenging for you to do the things you need to do to maintain a job, housing, or take care of people you care about?
	Continued use despite known or unknown problems socially and interpersonally (eg, interference with work, school, home)	Have you had conflict, stress, or lost connections with friends or family related to X use? Has use of X ever caused tension with work colleagues or health care providers?
	Elimination or reduction of important activities because of opioid use	Are there activities or hobbies that you used to spend time on that you've given up or spent less time on due to X use?
Compulsive use	Use in physically hazardous situations	Have you ever driven a vehicle or operated any machinery while using X? Has use of X ever left you vulnerable, for instance using while in a public area?
	Continued use despite known negative physical or psychological consequences	Have you ever been told by a medical provider that use of X was contributing to other physical or mental health issues that you've experienced?
Tolerance[1]	Need for increased doses for effect, reduced effect per dose, or both	Have you found that you need to use larger amounts of X to get the same effect, as compared to when you first started using?
Dependence[1]	Withdrawal symptoms when use is decreased, or using to relieve withdrawal	Do you notice uncomfortable symptoms when you stop using, such as…?

Severity of substance use disorder: **Mild**: 2–3 symptoms. **Moderate**: 4–5 symptoms. **Severe**: 6 or more symptoms.
X, substance being discussed.
[1] If a prescribed opioid is taken only as instructed, this item does not count toward a diagnosis of an opioid use disorder.

substances vary based on the laboratory, but most include amphetamines, cocaine, opiates, and benzodiazepines.

False positive results can occur with amphetamines, for example. In these cases, a follow-up (or "reflex") amphetamine confirmation testing will differentiate if the substance was an amphetamine, and if so, can further differentiate if it is a prescribed stimulant (such as prescription methylphenidate) or non-prescribed stimulant (such as methamphetamine). Cocaine is not a false positive substance on this test. Only certain benzodiazepines are tested for by these assays, typically those with oxazepam as a metabolite such as alprazolam, diazepam and lorazepam, thus a confirmation test can help detect these benzodiazepines. The category called "opiates" refers to natural opiates derived from the opium poppy and detects morphine derivatives, including codeine, morphine, heroin, hydromorphone (depending on concentration), thebaine, and their metabolites. In contrast, the urine opiate screen does not test for semisynthetic and synthetic opioids with morphine-like activity, such as fentanyl, methadone, buprenorphine, or oxycodone. Specific testing for these opioids via immunoassay tests needs to be ordered separately.

2. Liquid/gas chromatography and mass spectrometry (LC/GC MS) tests—This specialized testing is most often used to confirm the presence of substances and it may take days to weeks to obtain results. LC/GC MS is a highly specific, quantitative test used to confirm unexpected test results from screens, confirm if there was a false-positive or false-negative immunoassay test, monitor therapeutic levels of drugs, or detect subversion of urine samples. Interpreting the results of mass spectrometry requires some knowledge of substance metabolism. For example, a patient may be prescribed morphine but has a mass spectrometry test that returns positive for hydromorphone. This finding is expected since hydromorphone is a metabolite of morphine. Opioid and benzodiazepine metabolism charts are accessible online (https://thepainsource.com/metabolism-of-opioids/ and https://thepainsource.

com/metabolism-of-benzodiazepines/respectively). *If a substance is present on the LC/GC MS testing, it is unlikely to be a false positive.*

Treatment

A. Nonpharmacologic and Behavioral Health Treatments

Nonpharmacologic treatments are a crucial component of comprehensive care for patients with SUD alongside medication. These treatments can help manage cravings and triggers and address underlying psychological and social drivers. Healthcare for SUD is considered an essential health benefit, meaning that insurance must provide coverage for treatment. The SAMHSA website has a treatment program locator (findtreatment.gov). Clinicians may see their patients assessed with the American Society of Addiction Medicine (ASAM) Level of Care Designation, which incorporates substance use, mental health, and medical comorbidities to determine the appropriate setting for care given that substance use treatment facilities offer different certified levels of care (such as inpatient or intensive outpatient treatment).

Key nonpharmacologic treatments include:

- **Behavioral therapies**: Techniques like cognitive-behavioral therapy equip individuals with skills to identify and manage triggers, cope with cravings, and develop healthy coping mechanisms.
- **Mutual help**: Belonging to peer support groups like Alcoholics Anonymous or Narcotics Anonymous provides a safe space for sharing experiences, gaining encouragement, and learning from others in recovery. This also includes peer support from recovery specialists and community health workers with lived experience.
- **Mindfulness and stress management**: Practices like meditation and yoga can help manage cravings, reduce anxiety, and promote self-awareness, fostering overall well-being.
- **Complementary and integrative therapies:** Acupuncture, massage therapy, and other approaches may offer holistic support by managing physical discomfort and promoting relaxation.
- **Vocational and social support**: Addressing employment, housing, and other social drivers of health can create a more stable environment conducive to recovery.

These forms of evidence-based treatment should be discussed and offered when they align with the patient's care goals. Integrating these approaches with medication treatment and addressing underlying social drivers of health helps foster a holistic approach in addressing the complex issues surrounding SUDs and supporting long-term recovery.

Motivational interviewing is an evidence-based and patient-centered technique in clinical settings that uses supportive conversation to help individuals explore their ambivalence about change and build their own motivation to adopt healthier behaviors. Through reflective listening and open-ended questions, clinicians empower patients to identify their own goals and develop a plan for positive change. Motivational interviewing can be used within the context of SBIRT to collaborate with the patient on identifying next steps in treatment. Skills training for motivational interviewing can be found online (https://motivationalinterviewing.org/).

B. Mental Health Treatment

Concurrent treatment of co-occurring mental health disorders through integrative or collaborative care is critical for treatment success. Multiple studies have shown that individuals with SUDs are at increased risk for suicide. Untreated mental health disorders can worsen medication adherence and program retention. Addressing both conditions simultaneously increases the chances of successful recovery and improved overall health.

Mental health disorders can contribute to the development or continuation of SUD, since drugs, including opioids, can be used to cope with symptoms from conditions such as anxiety and depression. Addressing co-occurring conditions helps manage triggers, develop coping mechanisms, and build resilience, reducing the risk of returning to use. Individuals with co-occurring disorders often face greater stigma, health care disparities, and challenges accessing compassionate, evidence-based treatment, resulting in worse health outcomes.

C. Harm Reduction

Harm reduction is a powerful, evidence-based approach in SUD care, shifting the focus from solely achieving abstinence to minimizing the negative consequences associated with drug use. Harm reduction prioritizes patient health and well-being regardless of current usage and is an important approach in caring for persons who may not be ready to change their substance use patterns. It recognizes that not everyone is ready or able to commit to complete abstinence and that a return to drug use may be part of the SUD disease course.

By meeting people "where they're at" and offering nonjudgmental support, harm reduction empowers individuals to take steps toward better health and improved quality of life despite ongoing use. It helps reduce the morbidity and mortality associated with drug use (eg, HIV, hepatitis C, and accidental overdose) and strives to address social and structural barriers that perpetuate SUD and limit access to care. Harm reduction includes advocating for policies that reduce stigma and the criminalization of SUDs, while also addressing social drivers of health by promoting housing and employment opportunities for individuals with SUD.

Key harm reduction interventions include:

- **Naloxone distribution**: Naloxone reverses opioid overdoses; equipping communities with access to naloxone can save lives.
- **Syringe service programs and safe supplies**: Syringe service programs and safe supply kits provide clean needles and syringes, along with other drug use equipment, to reduce the risk of bloodborne infections like HIV, hepatitis B, and hepatitis C associated with shared

injecting equipment. These supplies can also include drug testing strips for fentanyl or xylazine.

- **Wound care and abscess management**: Addressing skin infections and other health complications arising from drug use promotes overall well-being.
- **Overdose safety planning**: Engaging the patient to identify higher-risk behaviors (eg, using alone or while intoxicated) and ways to mitigate their risks, such as identifying peer supports and treatment resources, helps reduce chances of opioid overdose. The Never Use Alone line is a resource for isolated patients intending to use (877-696-1996).
- **Non-stigmatizing language**: Stigma towards addiction within healthcare settings is a significant barrier to effective treatment and recovery for individuals with SUD. Evidence shows that healthcare professionals may hold negative and often unconscious beliefs about people with opioid use disorder (OUD), viewing them as weak-willed, morally deficient, less likely to respond to treatment, or undeserving of care when patients are described as a 'substance abuser' versus a 'person with a substance use disorder.' It is critical to role model and document with medically accurate, non-stigmatizing language with patients, families, and colleagues in conversation and documentation. Institutional stigma manifests itself in punitive policies or regulations that can further discourage patients from seeking timely care, disclosing drug use, remaining hospitalized until treatment is complete, or engaging in necessary upstream healthcare.

D. Racial Disparities and Culturally Informed Treatment

Documented racial disparities in medicine impact treatment recommendations and patient-provider communication. For OUD treatment, Black individuals are 42% and 47%, American Indian or Alaskan Native, Asian, Hawaiian/Pacific Islander individuals are 12% and 12%, and Hispanic Individuals are 22% and 20% less likely to receive buprenorphine or extended-release naltrexone, respectively, compared to White individuals. Treatment receipt of buprenorphine has also been shown to increase in higher-income and White communities compared to lower-income communities of color. Furthermore, contingency management, the most effective evidence-based approach to stimulant use disorder, is less accessible in rural areas as compared to urban settings. Racism and inequity must be addressed on the individual, interpersonal and systemic levels, and clinical settings can work to provide equitable and culturally informed treatment. Culturally informed treatment is adapting treatment to meet the needs of the individuals served, and should not replace effective medication treatment, as evidenced by a study that demonstrated that MOUD was a key driver in treatment completion where culturally informed treatment was studied.

OPIOID USE DISORDER (OUD)

ESSENTIALS OF DIAGNOSIS

- Treatment includes buprenorphine (sublingual, subcutaneous extended release), methadone (oral, through an opioid treatment program), or naltrexone (extended-release formulation only).
- In 2021, 75% of all accidental drug overdose deaths involved an opioid, yet only 1 in 5 American adults with OUD received medication treatment.

General Consideration

OUD continues to be a major public health crisis in the United States, and more opioid-involved overdose deaths (111,079) were reported in the United States in 2022 during the COVID-19 pandemic than in any previous year. The CDC's National Center for Health Statistics indicates that 2023 was the first year since 2018 with an annual decrease in drug overdose deaths. According to the 2022 NSDUH, an estimated 3.7% of American adults > 18 years old needed OUD treatment, though only 25.1% received any medications for OUD. In 2023, 3.1% of people (8.9 million) misused opioids in the past year. Rates of accidental overdose deaths have been driven in recent years by the introduction of potent synthetic opioids like nonpharmaceutical fentanyl into the drug supply.

While OUD prevalence rates vary across regions and demographics, certain groups are disproportionately affected. Risks of developing OUD are increased among (1) men, (2) persons of younger age (35–44 years old), and (3) persons who have adverse childhood experiences, another SUD, or psychiatric disease. Opioid overdose mortality rates increased by a factor of 7.7 between 2010 and 2020 among Black persons living in the United States, a far greater increase than in any other racial or ethnic group. While all groups experienced increases in overdose mortality in 2020, American Indian or Alaska Native individuals experienced the highest rate of overdose death, 30.8% higher than that among White American persons. The myriad factors underlying these disparities include systematized stigma toward drugs and individuals who use drugs, racialized incarceration rates, a history of biased drug policies in the United States, structural racism, and racial segregation of health care. Access to MOUD is disproportionately low among Black and other historically marginalized persons compared to White persons, who are more likely to live in communities with access to buprenorphine prescribers and who are more likely to receive MOUD.

OUD can present in the context of opioid intoxication or withdrawal, neither of which is sufficient alone to make the diagnosis of OUD. Instead, OUD can be identified through *patterns* of ongoing opioid use despite harmful consequences, such as medical comorbidities related to drug use (eg, skin and soft tissue infections, endocarditis), and is diagnosed using the *DSM-5* criteria (Table 48–1). Screening and history-taking may help diagnose OUD in patients with OUD without overt signs or symptoms of intoxication or withdrawal.

Clinical Findings

A. Diagnostic Criteria

The *DSM*-5 criteria can identify OUD and assess its severity. The diagnosis of OUD is made when at least 2 of the 11 *DSM-5* criteria are met over 12 months (Table 48–1). Notably, the *DSM*-5 recognizes tolerance and dependence as natural physiologic adaptations for any person with consistent opioid exposure. Therefore, tolerance and dependence alone in a patient on prescribed long-term opioids taking their medication as directed do not satisfy the criteria for OUD.

B. Laboratory Findings

Comprehensive urine or oral fluid drug testing before treatment can help establish a baseline for drug testing, facilitate conversation about recent drug use (eg, a patient may be unaware the oxycodone they are taking contains fentanyl), inform treatment options (eg, presence of opioids is a contraindication to starting naltrexone), and help with monitoring treatment over time. However, the diagnosis of OUD is made by clinical assessment, and testing is not required for diagnosis or treatment initiation. Urine testing should be performed regularly after treatment is initiated to inform medical management based on detection of the treatment medication (ie, buprenorphine or methadone), and if other nonprescribed opioids are absent.

Consider screening for infectious diseases (eg, HIV, hepatitis B, and hepatitis C serologies), especially if a patient reports opioid use by injection route. Hepatitis test results can inform evaluation for treatment, or preventive hepatitis A and hepatitis B vaccination. Positive HIV test results should trigger evaluation for treatment, and negative test results should inform future discussion of preexposure prophylaxis and targeted education.

Liver biochemical tests can establish baseline levels before starting MOUD.

A pregnancy test can inform treatment options; it is not advisable for patients to start naltrexone during pregnancy as this treatment has not been specifically studied in this population.

Complications

Infections from nonsterile injection drug use include cellulitis, abscesses at the injection site, endocarditis, or osteomyelitis. There is increased risk of infection with HIV, hepatitis B, and hepatitis C, especially if equipment is shared; there are reports of hepatitis C transmission with sharing equipment for intranasal insufflation. The risks are also increased for acquiring pneumonias and tuberculosis. The CDC recommends HIV preexposure prophylaxis for anyone with injection drug use and pneumococcal vaccination for anyone with any substance use.

Opioid-induced bowel syndrome with bloating, early satiety, and pain can occur since opioid agonists slow gut motility.

Opioid-induced hyperalgesia and co-occurring chronic pain. Opioid-induced hyperalgesia from long-term use of opioid agonists, including MOUD, can result in hyperalgesia, an increased sensitivity to pain. Patients with OUD and those taking MOUD have been shown to have a lower pain threshold and higher opioid tolerance when compared to patients without OUD or those with OUD who have not taken methadone as MOUD. Chronic pain is common among people with OUD, and it is important to note that OUD and chronic pain are not mutually exclusive. In one study, up to 48–74% of patients with OUD reported having chronic pain, and in another study, 80% of patients at an opiate treatment program (OTP) reported having chronic pain.

Accidental overdose and mortality rates are vastly increased in persons with OUD. Studies have shown up to 63 times the all-cause mortality rate in those with OUD compared to those without OUD or with OUD on MOUD. In 2021, 75% of all accidental drug overdose deaths involved an opioid.

Motor vehicle collisions and trauma are increased in persons with OUD.

Other complications from long-term opioid use include increased risk of hypogonadism and other hormonal disruptions, erectile dysfunction, fractures and bone density loss, delayed gastric emptying, and depression.

Treatment

OUD is a treatable medical condition with medications that have a robust evidence base to reduce morbidity and mortality. The three MOUDs approved by the FDA are buprenorphine, methadone, and extended-release naltrexone (Table 48–2). These medications are effective in reducing mortality even without concurrent counseling or mental health support. MOUD blocks or blunts the effects of nonprescribed opioids and reduces cravings to use opioids. Methadone and buprenorphine are also referred to as opioid agonist treatment—in contrast to naltrexone, an opioid antagonist—and can therefore also be administered to reduce or eliminate opioid withdrawal symptoms.

Randomized clinical trials showed treatment with methadone, buprenorphine, or extended-release naltrexone significantly reduced nonmedical opioid use relative to no medication treatment. Methadone and buprenorphine have been shown to reduce mortality from accidental overdose, mortality, and return to use in real-world studies. Studies have also found MOUD diminishes HIV and HCV transmission. In contrast, detoxification or medically supervised withdrawal alone (without subsequent medication treatment) is not an appropriate treatment for OUD; detoxification alone is associated with greater mortality and lower treatment retention compared to MOUD.

Table 48–2. Comparison of MOUD.

	Buprenorphine (sublingual)	Buprenorphine (extended-release)	Methadone	Naltrexone (extended-release)
μ-Opioid receptor effect	Partial agonist	Partial agonist	Full agonist	Antagonist
Patient selection	Mild to severe OUD; patient preference	Moderate to severe OUD Sublocade[1]: Start after stable sublingual buprenorphine 8–24 mg dose daily for ≥ 7 days. Brixadi[1]: Adults who are currently treated with sublingual buprenorphine-naloxone or have tolerated a single 4-mg dose of sublingual buprenorphine-naloxone	Moderate to severe OUD; high opioid tolerance; patient preference	Long-term stability in OUD treatment; in a setting without access to opioid agonist therapy; patient preference after being counseled on risks and benefits May treat concurrent AUD
Initiation and stabilization	Traditional: stop opioid use for 5–7 days (short acting) or 10–14 days (long acting or fentanyl) before initiation, confirm ≥ 3 withdrawal symptoms and urine toxicology. Low-dose initiation: continue full agonist during buprenorphine cross-titration (Table 48–4).	Sublocade: 300 mg subcutaneously every 4 weeks Brixadi (for weekly dosing): If buprenorphine 4 mg sublingual dose is tolerated, give buprenorphine 16 mg subcutaneously weekly. Add additional buprenorphine 8 mg subcutaneously weekly after 3 days for a total of 24 mg subcutaneously weekly	Recommended initial dose is 30–50 mg orally, with reassessment after 4 hours for sedation. Can give additional 10 mg orally as needed once for a maximum total dose of 50 mg orally on day 1. Dose increases in 5–10 mg increments, no more frequently than every 3–7 days (depending on clinical response), are recommended to avoid over-sedation, toxicity, or iatrogenic overdose.	Tester dose: 25–50 mg orally daily for 1–3 days
Usual effective dose	16–24 mg sublingually	100–300 mg subcutaneously monthly in the abdomen (Sublocade) 8–32 mg subcutaneously weekly (buttock, thigh, abdomen, upper arm) (Brixadi) 64–128 mg subcutaneously monthly (buttock, thigh, abdomen, upper arm) (Brixadi)	60–200 mg orally daily	50 mg orally daily 380 mg intramuscularly every 3–4 weeks Intramuscular preferred over oral formulation
Half-life	Sublingual: 24–42 hours	43–60 days (Sublocade) 3–5 days (weekly Brixadi) 19–26 days (monthly Brixadi)	8–59 hours; takes 3–5 days to reach steady state	Oral: 4 hours Intramuscular: 5–10 days
Advantages	Can be prescribed in office-based settings and picked up in pharmacies More flexible dosing schedule Lower risk of respiratory depression or sedation Lower risk of accidental overdose Can treat pain	Same as sublingual buprenorphine with ease of weekly or monthly dosing No risk of diversion	Improved treatment retention Reduces accidental overdose mortality Improved OUD remission Effective in pregnancy No maximum dosage Can treat pain More structured delivery setting	Does not cause sedation or respiratory depression; lower stigma in some settings; no risk of diversion; no dependence.

(*continued*)

Table 48–2. Comparison of MOUD. (continued)

	Buprenorphine (sublingual)	Buprenorphine (extended-release)	Methadone	Naltrexone (extended-release)
Precautions	Severe liver impairment—CYP450 metabolism; Risk of precipitated withdrawal during initiation; concurrent use of other CNS depressants (alcohol, benzodiazepines) can increase risk for respiratory depression (A); lower retention if doses < 16 mg sublingually daily	Injection-site reaction	Multiple drug-drug interactions with metabolism by cytochrome p450 Complex pharmacokinetics require careful monitoring Concurrent use of other CNS depressants (alcohol, benzodiazepines) can increase risk for respiratory depression (A)	Does not reduce cravings; can precipitate withdrawal if not adequate opioid abstinence; risk of fatal overdose if patient returns to use given loss of tolerance; inferior effect compared to opioid agonists treatment
Contraindications	Hypersensitivity; severe liver impairment	Hypersensitivity; patients with preexisting moderate to severe liver disease are not candidates	ECG QTc > 500 msecs; hypercapnia; respiratory depression (eg, severe COPD, severe OSA); hypersensitivity	Potential need for prescribed opioids (eg, upcoming surgeries, concurrent cancer pain)
Regulations and settings	Schedule III; can be prescribed by any clinician with a DEA license. Also used in OTP, inpatient settings	Schedule III; medication only available through REMS-certified pharmacies (ask for medication delivery) Provider must administer the injection.	Schedule II; can only be dispensed in OTP or acute hospital setting Not used in clinic settings Not visible on PDMP	Can be prescribed by any clinician with a DEA license Also used in OTP, inpatient settings

(A) The 2017 FDA Drug Safety Communication does not recommend holding opioid agonist therapy to patients solely on the basis of their taking benzodiazepines, because untreated OUD can pose a greater risk of morbidity and mortality.

AUD, alcohol use disorder; DEA, Drug Enforcement Administration; ER, extended-release; OSA, obstructive sleep apnea; OTP, opioid treatment program; OUD, opioid use disorder; PDMP, prescription drug monitoring program; REMS, Risk Evaluation and Mitigation Strategies.

[1] Only Brixadi (and not Sublocade) is considered safe in pregnancy.

Ideally, comprehensive treatment plans to support long-term remission include MOUD with behavioral therapy and access to harm reduction resources.

A. Pharmacotherapy

Buprenorphine as MOUD reduces opioid cravings and treats opioid withdrawal without producing euphoria and with a lower risk for adverse effects of full-agonist opioids. The combination sublingual product buprenorphine-naloxone or buprenorphine injection is generally recommended for MOUD and withdrawal treatment. The presence of naloxone in the combination product serves as a deterrent against nonprescribed injecting or intranasal opioid use; naloxone can induce withdrawal only if a person with opioid dependence injects or inhales buprenorphine-naloxone; if the buprenorphine-naloxone is taken sublingually as prescribed, a negligible amount of naloxone may be systemically absorbed and does not usually cause overt withdrawal. Nonetheless, naloxone frequently appears in urine toxicology results from patients taking buprenorphine-naloxone sublingually and some patients report mild withdrawal symptoms with use of the combination product.

Buprenorphine-naloxone as MOUD comes in three formulations: sublingual films and tablets and subcutaneous injection (extended-release). As of 2024, any clinician with a Drug Enforcement Administration (DEA) license can prescribe buprenorphine-naloxone for any indication; no X-waiver license is required.

There are two patient populations in which the mono-product is preferred. The first is in patients with decompensated cirrhosis, as the naloxone is not effectively eliminated by hepatic metabolism and can cause side effects such as nausea or headache. The other population is pregnant patients, as naloxone has not been formally studied in pregnancy. For patients with side effects to the combination product such as headache, a trial of the mono-product is a reasonable alternative. Extended-release buprenorphine comes in two formulations (Sublocade, dosed monthly, and Brixadi, dosed weekly or monthly). Only Brixadi is safe in pregnancy.

Buprenorphine has several unique properties: it (1) acts as a partial agonist at the μ-opioid receptor; (2) has a high affinity for the receptor with a long half-life of 24–44 hours; and (3) provides antagonism at the kappa opioid receptor, facilitating its use as MOUD. The partial agonism means that, in contrast to full agonists, increasing beyond moderate doses of buprenorphine typically does not result in greater opioid effects on respiratory depression and sedation. The minimum dose to provide overdose prevention is typically 8–16 mg sublingually based on ~10% μ-opioid receptor availability at this dose. Despite this high affinity, it is possible to effectively treat pain with short-acting full-agonist opioids (eg, oxycodone, hydromorphone) for patients receiving buprenorphine. Kappa-opioid receptor antagonism is thought to reduce cravings, dysphoria, depression, hyperalgesia, and cravings. Buprenorphine has wide individual variation in pharmacokinetics, has an analgesic half-life of 6–8 hours in contrast to its pharmacologic half-life, is excreted primarily in the feces with 10–30% excretion in the urine, extensively metabolized by the CYP450 system in the liver, and generally has fewer drug-drug interactions than methadone.

Buprenorphine-naloxone can be safely initiated in multiple settings: inpatient, office-based, or at home. Determining the appropriate initiation setting will rely on clinical judgment and may include consideration of a patient's experience with buprenorphine-naloxone and an assessment of their ability to manage initiation outside of clinical settings. Patients will need close monitoring during initiation and over the first few weeks. They should be educated on safe storage, administration with no food, tobacco smoking, or water until films/ tablets are completely dissolved (can take up to 10 minutes). The decision to initiate buprenorphine-naloxone via traditional (Table 48–3) or low-dose initiation (Table 48–4) depends on patient preference and clinical scenario. High-dose buprenorphine-naloxone initiation has been described with some success in case series of treating patients in the emergency department who have severe opioid withdrawal and have had challenges initiating buprenorphine-naloxone with other methods in the past, such as in individuals with long-term use of nonprescribed fentanyl.

The 2022 FDA Drug Safety Communication regarding sublingual buprenorphine-naloxone and dental problems (tooth decay, cavities, oral infections, and loss of teeth) provides the following guidance: "After the medicine is completely dissolved, take a large sip of water, swish it gently around your teeth and gums, and swallow. You should wait at least 1 hour before brushing your teeth to avoid damage to your teeth and give your mouth a chance to return to its natural state." However, multiple commentaries have noted that the study informing this warning was problematic, including that sublingual buprenorphine-naloxone for OUD was compared to transdermal patches for chronic pain, and thus question the validity of the study. Buprenorphine-naloxone is still recommended as a first-line, effective treatment for OUD.

1. Traditional initiation method for buprenorphine-naloxone—To reduce the risk of precipitated withdrawal, an opioid-free period (eg, discontinuation of all full agonists for about 8–72 hours) with medically supervised withdrawal is traditionally required as the initiation method of buprenorphine-naloxone for OUD (Table 48–3). This may be intolerable or inappropriate for some patients, such as (1) those who receive full opioid agonists as therapy for concurrent pain; (2) patients transitioning from very long-acting opioids (eg, methadone, fentanyl patches); and (3) patients who may have experienced precipitated withdrawal in the past or have significant fear of having this experience. For these patients, the low-dose initiation method (ie, "microdosing" or Bernese method) in which there is a period of concomitant buprenorphine-naloxone and full-agonist opioid cross-titration, may be more appropriate (Table 48–4).

2. Low dose initiation method for buprenorphine-naloxone—Low-dose initiation circumvents the need for stopping full-agonist opioids and going through a period of withdrawal before starting buprenorphine. Instead, small, and gradually increasing doses of buprenorphine-naloxone are administered with sufficient time between doses to establish equilibrium.

Table 48–3. Protocol for traditional initiation of buprenorphine-naloxone for patients with OUD in withdrawal or patient preference. All doses are for sublingual buprenorphine-naloxone.

Preparation	Discontinue full μ-opioid agonists at least 8–12 hours for short-acting opioids, 24–48 hours for extended-release formulations, and at least 72 hours for methadone. Confirm that patient has been prescribed and picked up comfort meds (Table 48–5). Start initiation of buprenorphine-naloxone only when there is mild-moderate opioid withdrawal (COWS ≥ 12) with at least three objective signs of withdrawal. Long-term non-pharmaceutical fentanyl use may require a lower starting trial dose of buprenorphine-naloxone or higher COWS score. Alternatively, consider high-dose buprenorphine-naloxone initiation (see text).
Day 1	Start buprenorphine-naloxone 2–4 mg sublingually. The risk of precipitated withdrawal is reduced by starting buprenorphine at doses < 2 mg. Monitor over 60–90 minutes for precipitated withdrawal and treat if it develops. Reassess symptoms every 2–4 hours. If withdrawal persists, repeat doses of buprenorphine-naloxone 2–4 mg sublingually every 2 hours to a maximum of 8 mg. Once it has been established that the initial dose of buprenorphine-naloxone is well tolerated, dose titration can be achieved fairly quickly.
Day 2	Give total buprenorphine-naloxone dose from Day 1. Give additional buprenorphine-naloxone 2–4 mg sublingually every 2–4 hours, up to 16 mg total.
Day 3–14	Ongoing titration. If the patient's therapeutic goals are met, the dose need not be adjusted. If continued cravings or withdrawal are present without sedation, increase dose of sublingual buprenorphine-naloxone by 2–4 mg daily to an effective dose of 16–24 mg daily. It can take 1–2 weeks to achieve a stable dose outpatient.

COWS, Clinical Opioid Withdrawal Scale.

Table 48–4. Two sample low-dose initiation protocols for buprenorphine.*

	For patients maintained on prescribed full agonist opioids, patients transitioning from very long-acting opioids (eg, moderate- to high-dose methadone, chronic non-prescribed fentanyl use) or patient preference.		
Options	Buprenorphine initiation with transdermal patch (A) and sublingual	Buprenorphine initiation with sublingual tab/film (B) only	Full agonist
Patient selection	Less risk for precipitated withdrawal; does not require cutting films/ tablets	Transdermal formulation may not be available or may be cost prohibitive	
Day 1	Transdermal 40 mcg/hour (2–20 mcg/hour patches)	0.5 mg sublingually once (C)	Continue baseline full-agonist dose in most cases until buprenorphine-naloxone dosing is at least 8–12 mg sublingually daily
Day 2	No changes	0.5 mg sublingually every 12 hours	
Day 3	1 mg sublingually every 12 hours	1 mg sublingually every 12 hours	
Day 4	1 mg sublingually every 8 hours	1 mg sublingually every 8 hours	
Day 5	2 mg sublingually every 12 hours	2 mg sublingually every 12 hours	
Day 6	4 mg sublingually every 12 hours	4 mg sublingually every 12 hours	
Day 7	12 mg sublingually in the morning[1]	12 mg sublingually in the morning[1]	Can discontinue or taper off full opioid agonist (D)
Day 8	Further adjustment by clinician	Further adjustment by clinician	

*Protocol applies to initiation of any sublingual buprenorphine formulation (the monoproduct or the combination buprenorphine-naloxone product).

[1] Continue to adjust buprenorphine dose to symptoms by 2–4 mg sublingually daily. This protocol lists recommended titration steps. Protocol steps can be paused/continued without progression for several days as needed due to patient discomfort, clinical scenario, etc. Total daily dose can be consolidated once effective dose is reached. Return to a lower dosing level if a patient becomes sedate.

(A) Maintain the transdermal patches until they expire in 7 days, then remove and do not replace. Note that it takes 3–4 days for a transdermal patch to reach steady state. The buprenorphine patch is FDA approved for pain. If the indication is opioid use disorder, the medication may not be covered for outpatients.

(B) Films may be preferred given they are easier to split.

(C) A 0.5 mg sublingual dose can be achieved by cutting a 2 mg buprenorphine film or tablet in quarters. If this is not permitted by inpatient pharmacies, use options for initiation by starting with transdermal or intravenous formulations, then rotating to sublingual.

(D) Short-acting full-opioid agonists may be appropriate to continue in some cases if clinically indicated (eg, treating concurrent acute pain like a traumatic fracture, terminal end-of-life pain).

Full-agonist opioids are continued while buprenorphine-naloxone is started and titrated to a therapeutic dose (usually 16–24 mg sublingually for OUD), via the low-dose method, at which time the full-agonist opioids may be stopped, tapered off, or continued depending on the clinical situation. Outpatient low-dose initiation is most effective when patients or caregivers can follow multi-step medication instructions and respond to telephone or nursing checks 1–2 days after initiation and then 3–7 days later, or with changes in the dosing regimen, to assess symptoms and triage adverse effects.

Low-dose initiation can be performed in any setting: administered inpatient or prescribed in the outpatient setting, and with any formulation of buprenorphine. Published protocols vary by timelines (eg, longer in outpatient settings or patients on moderate- to high-dose methadone, rapid for inpatient settings) and the buprenorphine-naloxone formulation used. Importantly, initiation protocols can be modified or paused if a patient experiences intolerable worry, withdrawal symptoms, or pain flares. See Table 48–4 for a sample of an initiation protocol using the buprenorphine patch and sublingual forms. Importantly, *the full-agonist opioid must be maintained during the initial phases of buprenorphine initiation to prevent a decrease in total opioid load resulting in iatrogenic withdrawal.* In the inpatient setting, non-MOUD opioid agonists can be administered. In the outpatient setting, non-MOUD opioid agonists cannot legally be prescribed, and the patient should continue whichever opioid they have been using. For example, hospitalized patients who use non-prescribed fentanyl long-term can be administered oxycodone immediate release 15–20 mg orally every 3 hours as needed for cravings or withdrawal symptoms as the non-MOUD opioid agonist until buprenorphine reaches steady state.

3. Withdrawal precipitated by the use of buprenorphine—If buprenorphine is introduced when opioid receptors are occupied by full agonists, buprenorphine will outcompete the full agonist to exert a partial opioid effect. The resulting shift from full opioid effect to partial opioid effect manifests as opioid withdrawal. This precipitated

Table 48–5. Opioid withdrawal treatment with nonopioid adjuncts ("comfort meds").

Symptom	Medication	Dose (oral)	Frequency	Other
Nausea	Odansetron	4 mg	Every 6 hours, as needed	Can prolong QTc
Pain, headache	Acetaminophen Ibuprofen	650 mg 400–800 mg	Every 6 hours as needed Every 8 hours as needed	Avoid in liver failure Avoid in renal failure
Diarrhea	Loperamide	4 mg	Every 6 hours, as needed	
Anxiety	Hydroxyzine	25–50 mg	Every 6 hours, as needed	Caution if patient sedation or in older adults
Tremors, sweating	Clonidine	0.1 mg	Every 8 hours, as needed	Caution if low blood pressure or heart rate

withdrawal can be treated by reducing the relative opioid deficit (ie, adding more buprenorphine or full agonist), or by pausing initiation and using nonopioid "comfort meds" to alleviate withdrawal symptoms (Table 48–5). Initiation can be reattempted in 24 hours.

4. Methadone—Despite widely documented effectiveness of methadone treatment, it remains a schedule II drug with federal regulations limiting its use as MOUD to approved OTPs, which exacerbates an ongoing treatment gap of nearly 1 million people with OUD not receiving treatment. Methadone as MOUD is dosed to reduce opioid cravings and withdrawal symptoms, may blunt the euphoric effects of other opioids, and may be better at retaining patients in treatment compared to buprenorphine and extended-release naltrexone. About 1500 federally certified OTPs in the United States offer methadone treatment to people who meet admission criteria. Historically, it has been difficult to get take-home bottles of methadone, but in 2024, federal regulations changed to allow a greater role for provider judgment in making decisions about take-home methadone. A patient now can be eligible for up to 7 take-home doses after only 14 days of treatment.

If a patient begins methadone treatment in the hospital, that patient needs to be connected to an OTP for ongoing medication. OTP connection should be facilitated in advance of discharge. For patients discharged to the community, discharge paperwork must include a "last dose letter" that includes the date, time, and dose of the last methadone administered so that the OTP can continue titration, rather than starting the patient from the standard initiation dose of up to 50 mg daily. If a patient is transferred to a facility that does not administer methadone, then an intake must be arranged at an OTP that will provide dosing. Previously, only in-person intakes were permitted; regulations now allow use of telehealth, but coordination is needed between the hospital and the OTP. Ideally, there is ample lead-time (~1 week) to plan for logistical considerations. The average methadone half-life of 24 hours facilitates once daily dosing in methadone treatment, although the analgesic half-life is 6–8 hours. Methadone treatment initiation starts with doses of approximately 15–50 mg daily and are titrated to balance cravings with adverse effects, typically reaching stable doses of 80–200 mg in the era of fentanyl. Tapering off of methadone after a period of sustained stability may be considered, however longer lengths (even a lifetime) are associated with better outcomes.

5. Naltrexone—Naltrexone is an opioid antagonist at the μ-opioid receptor, so it blocks the euphoric and sedative effects of opioid agonists. Unlike buprenorphine and methadone, naltrexone does not treat physical dependence or withdrawal symptoms that may be associated with OUD. It also does not infer the same protective effect against overdose as buprenorphine. *Naltrexone should only be initiated in a person who has completed opioid withdrawal, since it will otherwise precipitate withdrawal.* The SAMHSA generally recommends that a person wait 7 days after their last use of short-acting opioids or 10–14 days after their last use of long-acting opioids before starting naltrexone to reduce the risk of precipitated, acute opioid withdrawal. Naltrexone extended release is the preferred MOUD because the long-acting formulation improves adherence to the medication.

B. Monitoring Pharmacotherapy

After treatment initiation, regular follow-up should be continued for related medical issues. Additionally, provider engagement surrounding adherence to MOUD, overdose risk mitigation techniques, and discussion of triggers and recovery strategies should be continued. Behavioral treatments (eg, psychotherapy) should be offered if not already utilized.

For patients receiving methadone, the OTP will up-titrate and monitor the dosing, so best practice includes having the patient sign a release of information with the OTP. On urine toxicology testing, recent use of methadone is noted by a positive EDDP (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine) test, a metabolite of methadone. Because methadone is long acting and lipophilic, EDDP may be present in the urine for weeks to months after last use for patients receiving methadone long-term.

For patients using sublingual buprenorphine, typical follow-up is every 1–2 weeks after initiation for monitoring and titration. Visits should remain frequent while titrating to an effective dose of at least 16 mg sublingually daily, and once stable, visits can be spaced out to every 1–3 months depending on the stability of remission. Urine toxicology tests should also be attained at regular intervals, with the goal of confirming the presence of buprenorphine metabolites (norbuprenorphine) and the absence of non-buprenorphine opioids. For patients taking subcutaneous, extended-release buprenorphine, the presence of buprenorphine does not need to be monitored as treatment is administered in clinic. However, urine toxicology testing can be administered to evaluate if other non-prescribed substances are present.

For patients using extended-release naltrexone, the monitoring is similar for extended-release buprenorphine, as the product is directly administered. Urine toxicology testing should be tailored to the patient scenario.

OPIOID INTOXICATION & OVERDOSE

General Considerations

Opioid intoxication is the physiologic response to the acute effects of an opioid agonist through activation of the μ-opioid receptor in the CNS.

Opioid overdose is the most severe form of opioid intoxication syndrome. Overdose is a potentially fatal state in which opioids cause suppression of the respiratory centers in the brainstem and medulla. Opioid overdose is a medical emergency and requires immediate medical management. Of note, respiratory depression is preceded by the warning sign of sedation.

Mild to moderate intoxication, such as euphoria or sedation, is not life-threatening and occurs on a spectrum such that the presence of opioid intoxication is not always obvious on physical examination.

Tolerance, or the reduced responsiveness to a substance over time so that increased doses are needed to achieve the desired effect, is a critical concept in the context of opioid use. Tolerance is a predictor of overdose risk and severity; in patients with high tolerance, the required dose to cause respiratory depression may be lower than the dose required to produce the desired level of euphoria. Additionally, individuals who may lose tolerance (ie, post-hospitalization incarceration, or a period of remission) are at higher risk for opioid overdose upon re-exposure to the doses of opioids that they used previously.

Clinical Findings

A. Symptoms and Signs

Opioid intoxication involves a spectrum of symptoms including the combination of altered mental status, respiratory depression, and miotic pupils. **Overdose** should be diagnosed when the respiratory rate is < 8 breaths per minute, signs of cyanosis are present, or if the patient is nonresponsive. Severe intoxication presents as overdose, which can be fatal if not intervened upon within the window of reversibility.

Physical examination findings of opioid intoxication include miosis with decreased blood pressure, heart rate, respiratory rate, or a combination of these. Other signs that suggest opioid use are dependent on the route of ingestion; oral, inhaled (“smoked”), intravenous, intranasal/insufflation (“snorting”), rectal (“booty bumping”), intramuscular, and subcutaneous (“skin popping”). For example, patients may have signs of skin irritation from frequent injections that resemble bruises with small dots (“track marks”), or skin and soft-tissue infections related to drug use.

Additional symptoms of opioid intoxication may include nausea, vomiting, confusion, constipation, depression, dry mouth (which can result in tooth decay), and pruritus.

B. Laboratory Findings

At the time of the opioid overdose, toxicology testing should be done to confirm which substances are present and to further guide management. Not all substances (such as xylazine) will be found on basic urine toxicology testing. Consent for this testing requires consent from patients who are mentating with capacity but should be performed in nonresponsive patients without consent to inform treatment.

Treatment

A. General Measures

To manage an overdose, increasingly intensive measures are needed, initiated in the following order:

1. Verbal warning (ie, “Are you awake? I am going to administer naloxone because I am worried you are overdosing”).
2. Sternal rub.
3. If no response, then immediately administer naloxone 0.4–0.8 mg intravenously or intranasally.

B. Specific Measures

Naloxone can be administered intranasally or intravenously at 0.4–0.8 mg per dose. Naloxone will reverse CNS effects of opioids; onset of action is 2 minutes, and duration of action is 30–90 minutes. Naloxone can cause opioid withdrawal symptoms that are distressing but can be life-saving. Additional basic life support with frequent vital signs monitoring should be instituted while waiting for the naloxone to take effect; adequate intravenous access is required to administer supportive medications (such as fluids) and oxygen should be administered via nasal cannula. If cyanosis does not resolve, intubation may be necessary.

When a long-acting opioid has been used (eg, prolonged fentanyl use, methadone) and respiratory depression and sedation persist after the effect of the initial naloxone dose has worn off, a continuous naloxone infusion may be warranted. For patients receiving prescribed opioids for pain who may have respiratory depression and risk of accidental overdose, a lower tester dose of naloxone (0.04 mg intravenously) can be administered to test for reversal of opioid-related respiratory sedation and depression without entirely reversing opioid analgesia.

Of note, nonprescribed opioid overdoses commonly include other substances, including other cognitive and respiratory depressants, such as benzodiazepines, alcohol, and xylazine. Naloxone reverses only the opioid effects; it does not reverse respiratory sedation from nonopioid substances. In these instances, continued supportive care and advanced cardiopulmonary support is indicated if severe respiratory depression is present until the substance has metabolized.

OPIOID WITHDRAWAL

General Considerations

Opioid withdrawal can be agonizing; however, it is typically nonfatal in the absence of persistent and severe electrolyte imbalances due to severe diarrhea and vomiting. The duration and onset of the acute withdrawal phase depends on the opioid used. Opioids with longer half-lives result in later onset (eg, methadone, extended-release oxycodone) and typically have a longer duration of the acute withdrawal phase. The onset of non-pharmaceutical fentanyl withdrawal can be unpredictable and protracted as a result of a combination of various analogs of fentanyl in the substance used.

Clinical Findings

A. Symptoms and Signs

Opioid withdrawal is marked by nausea, vomiting, diarrhea, chills and sweating, tremors, muscle and bone pain, and anxiety. Clinically this can look similar to a severe case of influenza, or other viral or bacterial infections. As is the case with most SUDs, avoiding or minimizing the significant dysphoria and physical discomfort of the withdrawal state is often a primary trigger to continued use. The degree of opioid withdrawal is measured using the Clinical Opioid Withdrawal Scale (COWS) which incorporates subjective and objective findings (https://nida.nih.gov/sites/default/files/ClinicalOpiateWithdrawalScale.pdf). Moderate withdrawal is typically in the COWS 13–24 range. The COWS score is useful both to measure response to withdrawal management and to guide buprenorphine initiation.

B. Laboratory Findings

The immunoassay and the LC/GC MS tests generally demonstrate the presence of opioids within the past 1–3 days. Heroin is typically metabolized to morphine within 8 hours so it is only detectable within less than 1 day after use. In contrast, prolonged nonpharmaceutical fentanyl has been found to be present for up to 3 weeks after last use. Methadone typically can be detected for 7 days, and buprenorphine for 1–11 days after use.

False-positive results can be caused by dextromethorphan, diphenhydramine, poppy seeds, quinine, quinolones, rifampin, and verapamil. False-negative results occur when the opioid is present at a level lower than the threshold for detection. Specimen contamination or tampering can be evaluated through the urine test results using temperature, creatinine concentration, pH, and specific gravity. Temperature strips should show urine is 90–100°F within 4 minutes of collection. Human urine has a pH level between 3 and 11, specific gravity between 1.002–1.020, urine creatinine > 20 mg/dL (< 5 mg/dL is inconsistent with human urine in cases of urine tampering by dilution), and creatinine concentration < 5 ng/mL. Oxidant tests can indicate the addition of bleach or another oxidant. Results outside these ranges suggest contamination or adulteration, in which case the testing should be repeated.

Treatment

Managing opioid withdrawal is important, as unmanaged opioid withdrawal is a well-described reason patients provide for leaving medical care before recommended by the medical team or for using non-prescribed substances while hospitalized. The most effective method to manage opioid withdrawal is to initiate medication treatment like methadone or buprenorphine. Opioid withdrawal management incorporates both opioid (including MOUD) and nonopioid pharmacologic interventions (Table 48–5). Options can vary by clinical site.

A. Treatment in the Emergency Department or Inpatient Setting

For patients who come to the emergency department or those who are hospitalized, any opioid can legally be administered to manage opioid withdrawal, including MOUD or other full-agonist opioids. Special hospital or provider Drug Enforcement Administration (DEA) licensing is not required. MOUD should be offered as first-line treatment for opioid withdrawal and OUD. For the emergency department, the “Three Day Rule” is an emergency treatment clause that allows providers outside of an Opioid Treatment Program (OTP) to administer, but not dispense, narcotics for the treatment of opioid withdrawal. This law was expanded in 2020 to allow for the dispensing of narcotics with special permission. If MOUD initiation is declined, short-acting opioids or low-dose methadone (30–50 mg orally daily) can be administered while the patient is hospitalized to manage withdrawal symptoms. These opioids cannot legally be prescribed on discharge for OUD treatment outside of an OTP.

The titration of MOUD to an effective dose that quells cravings and opioid withdrawal symptoms can take time. For patients who report recent use of long-acting opioids such as non-pharmaceutical fentanyl or methadone, short-acting opioids can be administered as a bridge while the long-acting opioid is metabolized but before the buprenorphine can be initiated (using a traditional initiation protocol) (Table 48–3) or while buprenorphine dosage is subtherapeutic (using a low dose, "microdosing," gradual up-titration, or bridging protocol) (Table 48–4). Similarly, short-acting opioids can be administered as a bridge to ward off opioid withdrawal symptoms until methadone is titrated to therapeutic doses, which can take weeks.

B. Outpatient Treatment

Opioid prescribing is tightly regulated by the 1974 Narcotic Addict Treatment Act, which states that narcotics cannot be used to manage opioid withdrawal outside of federally designated OTPs (eg, official methadone clinics). Any clinician with a DEA license, however, can prescribe office-based buprenorphine treatment as MOUD and for management of withdrawal (Table 48–3). Patients interested in outpatient management of OUD and opioid withdrawal with methadone need to seek care through an OTP that will administer methadone, as it cannot be prescribed.

ALCOHOL USE DISORDER (AUD)

ESSENTIALS OF DIAGNOSIS

- Continued alcohol drinking despite consequences of medical and social contraindications, life disruptions, or impairment in social and occupational functioning.
- Physiologic dependence manifests by withdrawal when intake is interrupted; tolerance manifests by the need for more alcohol intake to maintain the same effect.
- Evidence of alcohol-associated illnesses include liver disease, cerebellar degeneration, pancreatitis, or alcohol-related injuries.

General Considerations

Alcohol use is a leading cause of morbidity and mortality, with potential harms resulting from both acute and chronic use. According to the 2023 National Survey on Drug Use and Health, 16.4 million people ages 12 and older reported heavy alcohol use in the past month (5 or more drinks on any day or 15 or more per week for men, or 4 or more drinks on any day or 8 or more drinks per week for women). Ten percent of the American adult population over 12 years old, or 23.9 million people, reported AUD in the past year. Excessive alcohol use contributed to over 178,000 deaths each year.

Alcoholic beverages contain ethanol, a simple compound that is small and lipophilic, allowing it to easily cross the blood-brain barrier and interact with multiple neurotransmitter systems. Clinically, this can manifest acutely with decreased level of consciousness, slurred speech, and impaired balance and gait. The activation of γ-aminobutyric acid (GABA)-A receptors is believed to play a role in dopamine release in the mesolimbic dopamine system, the highly conserved pathway central to addictive disorders. Research has shown that there is far more complexity to the neurochemistry of ethanol beyond GABA. Ethanol interacts with other receptors, including N-methyl-D-aspartate (NMDA), glycine, neuronal nicotinic, and 5-hydroxytryptamine type 3 (5-HT3) receptors. It can also cross the cell membrane and directly influence second-messenger pathways.

When evaluating patients who use alcohol, there is a spectrum of use: the majority of people are either abstinent or follow safe drinking limits; however, some persons have unhealthy use, defined as either exceeding safe limits or having an AUD. The National Institute on Alcohol Abuse and Alcoholism (NIAAA) defines safe drinking limits as 2 drinks or less in a day for men and 1 drink or less in a day for women (< 14 drinks/week in men, and < 7 drinks/week in women). Persons over age 65 follow the same recommendations as women. A drink is defined by the CDC as 12-oz of beer, 8-oz of malt liquor, 5-oz of wine, or 1.5-oz or a "shot" of 80-proof distilled spirits or liquor. The NIAAA has an online drinking calculator that can be used to determine if the person is adhering to safe limits (https://rethinkingdrinking.niaaa.nih.gov/tools/calculators). People who exceed safe limits drink *> four drinks per day or 14 drinks per week for men or > three drinks per day or seven drinks per week for women.* A person may move bidirectionally through these classifiers throughout their lifespan.

AUD is a clinical diagnosis by *DSM-5* criteria, including loss of control with heavy and persistent use, drinking despite consequences, compulsion to use, cravings, tolerance, and withdrawal. There are no known safe drinking limits. A recent commentary suggested that for those without AUD or comorbidities (including chronic illness, driving a vehicle, or pregnancy), drinking one standard drink equivalent per day with interspersed abstinent days may not constitute a meaningful risk to health.

As of 2023, the prevalence of AUD among men is 12.1% compared to 8.3% for women. Women often delay seeking help, and when they do, they tend to seek it in medical or mental health settings. Treatment completion rates are influenced by intersectional social factors, including gender, race, and ethnicity, such that 10–12% fewer minoritized women complete treatment compared to White men. Adoption and twin studies suggest some genetic influence.

Ethnic distinctions are important—eg, 40% of Japanese individuals have aldehyde dehydrogenase deficiency, causing adverse side effects from alcohol, and a decreased risk of developing AUD. Patients with AUD have a higher prevalence of lifetime psychiatric disorders. Depression is often present and should be evaluated carefully and treated. Alcohol significantly increases the risk of death by suicide and has been associated with violent crimes and domestic assault.

There are several screening instruments that may help identify an AUD. One of the most useful is the **Alcohol Use Disorder Identification Test (AUDIT)** (see Table 1–6).

Clinical Findings

A. Symptoms and Signs

A distinction needs to be made between primary AUD (when there is no other major psychiatric diagnosis) and secondary AUD (when alcohol is used as self-medication for major underlying psychiatric problems such as schizophrenia or affective disorder). This distinction is important, since the latter requires treatment for the specific psychiatric problem. In primary and secondary AUD, at-risk drinking can be distinguished from AUD by taking a careful psychiatric history and evaluating the degree to which recurrent drinking impacts social role functioning and physical safety of the individual. Using The *DSM-5* criteria are useful in diagnosing AUD (Table 48–1).

B. Laboratory Tests

1. Urine alcohol testing—Testing for alcohol consumption is mostly performed in the urine, either directly by measuring ethanol (which is quickly eliminated so a test can only detect very recent use), or measuring ethyl glucuronide, an ethanol metabolite that is typically positive for alcohol use in past 3 days.

2. Blood alcohol testing—For a 70-kg person, 1.5-oz of whiskey, a 5-oz glass of wine, or a 12-oz bottle of beer (roughly 15 g of alcohol) may raise the level of alcohol in the blood by 25 mg/dL. For a 50-kg person, the blood alcohol level would rise even higher (35 mg/dL) with the same consumption. Blood alcohol levels < 50 mg/dL rarely cause significant motor dysfunction (the legal limit for driving under the influence is commonly 80 mg/dL). Intoxication as manifested by ataxia, dysarthria, and nausea and vomiting often indicates a blood level > 150 mg/dL, and lethal blood levels range from 350 mg/dL to 900 mg/dL. Hazardous drinking can be measured by blood phosphatidylethanol levels, where a value of ≥ 0.22 mcmol/L is more sensitive and specific than urine alcohol testing.

Ethanol may contribute to the presence of an otherwise unexplained osmolar gap. There may also be increased serum liver biochemical tests, uric acid, and triglycerides and decreased serum potassium and magnesium. The most definitive biologic marker for chronic AUD is carbohydrate deficient transferrin, which can detect heavy use (60 mg/day over 7–10 days) with high specificity. Other useful tests for diagnosing AUD are γ-glutamyl transpeptidase (GGT) measurement (levels > 30 U/L are suggestive of heavy drinking) and mean corpuscular volume (MCV) (> 95 fL in men and > 100 fL in women). If both are elevated, patients should be screened for unsafe alcohol use. Use of other recreational drugs with alcohol can interfere with the significance of these tests.

Complications

The medical, economic, and psychosocial problems of AUD are staggering. Alcohol use affects many organ systems, often in dose-dependent relationships, and contributes to over 200 conditions. Current research suggests no safe drinking level, given that some risks, such as breast cancer, can begin at low levels of use.

1. Liver disease—Ninety percent of alcohol is metabolized by the liver, thus exposing the liver to both alcohol and its toxic metabolites. Alcohol-related liver injury and disease (ALD) includes steatosis, steatohepatitis, alcohol-associated hepatitis, fibrosis and scarring, and HCC. In most ALD, not drinking alcohol can prevent further liver damage and improve survival rates.

2. Pancreatitis—Alcohol is the leading cause of chronic pancreatitis and the second leading cause of acute pancreatitis. Cigarette smoking increases the risk of both types of pancreatitis and can exacerbate risk when used in combination with alcohol.

3. GI inflammation—GI mucosal inflammation, bleeding, and GERD can be due to damage of the epithelial lining by alcohol.

4. Heart disease and stroke—Heavy alcohol use causes 9000 deaths a year due to alcohol-related heart disease and stroke. Even low-level alcohol use contributes to increased risk for hypertension, arrhythmia (specifically atrial fibrillation), cardiomyopathy, and MI.

5. Cancer—Alcohol and its metabolites are recognized as carcinogens. Alcohol use has been associated with higher risk of head and neck cancers (oral cavity, larynx, pharynx, esophageal), GI cancer (liver, stomach, colorectal), and breast cancer in women.

6. Myopathy, fractures—Chronic, heavy alcohol use increases the risk of midline muscle atrophy and weakness. Daily drinking of > 1.5–2 drinks a day can increase the risk of fractures due to disruption in bone remodeling, as well as increased risk of falls with heavy alcohol use.

7. Gout—The risk of developing and flaring of gout increase in a dose-dependent manner with alcohol use.

8. Nervous system—Alcohol contributes to peripheral and central neuropathies through both direct neurotoxicity and indirectly through inflammation and nutritional deficiencies. Peripheral neuropathies include symmetrical ‘stocking-glove’ sensory loss, postural hypotension, and erectile dysfunction. Cognitive effects include dementia, loss of memory and attention, and reduced brain volume.

9. Fetal alcohol syndrome—No amount of alcohol is known to be entirely safe in pregnancy. Fetal alcohol syndrome

Table 48–6. FDA-approved medications for treatment of AUD.

Medication	First-Line Agents		Second-Line Agent
	Naltrexone	**Acamprosate**	**Disulfiram**
Effect	Reduces heavy alcohol use (NNT 12) and daily drinking; reduces return to any drinking (NNT 20); reduces cravings	Reduces return to any drinking (NNT 12); reduces drinking days overall; more effective than naltrexone at promoting abstinence; less effective than naltrexone at reducing cravings	Acts as a deterrent to drinking No better than placebo for return to any drinking or abstinence The disulfiram-alcohol reaction begins 10–30 minutes after drinking alcohol, can last several hours, and includes nausea, vomiting, facial flushing, headache, dizziness, sweating
Dosing	Goal dose: Daily: 50–100 mg orally Extended-release: 380 mg ventrogluteal intramuscularly every 4 weeks	666 mg orally three times daily	250–500 mg orally daily
Patient selection	Can be given to patients currently drinking	Consider for patients with OUD on MOUD (methadone, buprenorphine) or who require opioids High pill burden	Largest benefit with supervised dosing by a support person
Contraindications	Current or anticipated opioid use. Decompensated cirrhosis or acute liver failure. Generally safe in Child-Pugh class A and B. Caution in Child-Pugh class C. Intramuscular naltrexone avoids first pass metabolism and may be safer if given for alcohol related liver disease and cirrhosis.	Do not use if CrCl < 30 mL/minute. For CrCl 30–50 mL/minute, reduce dose to 333 mg orally three times daily No dose adjustment for liver impairment	Severe cardiac disease, psychosis, hypersensitivity Generally safe in CTP A; use caution in CTP class B
Side effects[1]	Nausea, vomiting, headache, dizziness	Diarrhea, vomiting, insomnia, anxiety	Headache, metallic taste in mouth
Mechanism of action	Nonselective opioid antagonist blocks indirect release of endogenous opioids due to the reduced rewarding effect of alcohol	Glutamate receptor modulator thought to restore balance between GABA and glutamate systems disrupted by alcohol	Inhibits the breakdown of aldehyde dehydrogenase resulting in buildup of acetaldehyde if alcohol ingested causing aversive symptoms of disulfiram-alcohol reaction
Management	If liver function studies are 3–5 times the upper limits of normal, pursue additional workup, but not a contraindication to initiation. Will cause precipitated opioid withdrawal if administered to a patient currently on opioids.	Most effective when started after completion of medically managed alcohol withdrawal	Should be taken at least 12 or more hours after last alcohol use. Avoid alcohol containing products (eg, mouthwash, sanitizer).

[1] Side effects tend to lessen with use for naltrexone and acamprosate.

AUD, alcohol use disorder; CrCl, creatinine clearance; GABA, γ-aminobutyric acid; MOUD, medication for opioid use disorder; NNT, number needed to treat; OUD, opioid use disorder.

includes a spectrum of physical, behavioral, and cognitive impairments resulting from prenatal alcohol exposure.

Treatment

Only 7.9% of Americans aged 12 and older with AUD in 2023 received any treatment. Treatment for AUD has been shown to increase rates of not drinking, reduce return to drinking, and reduce symptoms of protracted alcohol withdrawal.

Pharmacologic Treatments

The three FDA-approved medications to treat AUD are two first-line agents, naltrexone and acamprosate, and the second-line agent disulfiram (Table 48–6). Non-FDA approved treatments for patients intolerant to first-line agents or due to patient preference include gabapentin, topiramate, and baclofen.

ACUTE ALCOHOL INTOXICATION

Clinical Findings

A. Symptoms and Signs

The signs of alcoholic intoxication depend on serum ethanol concentrations and can vary by person. Signs can include slurred speech, incoordination, drowsiness, psychomotor dysfunction, disinhibition, dysarthria, ataxia, and nystagmus. Hypotension and tachycardia may result from peripheral vasodilation from ethanol or due to vomiting and volume loss.

At serum alcohol concentrations between 20 mg/dL and 100 mg/dL, people may feel euphoria and have mild deficits in attention, cognition, and physical coordination. For concentrations between 100 mg/dL and 200 mg/dL, symptoms include greater deficits in coordination, motor skills, judgement, and speech, as well as mood variability. With severe intoxication at concentrations between 200 mg/dL and 300 mg/dL, patients may present with confusion, nausea, and vomiting. At concentrations > 300 mg/dL, symptoms can include loss of consciousness and respiratory depression. In very severe cases, intoxication can include seizures, shock syndrome, and death. Some individuals with high tolerance to ethanol from chronic use may show few signs of intoxication at concentrations > 300 mg/dL. Serious overdoses are frequently due to a combination of alcohol with other sedatives or drugs.

B. Laboratory Tests

Laboratory testing is usually not needed for patients with isolated mild alcohol intoxication. For more complicated or severe cases, acute intoxication can cause metabolic derangements such as hypoglycemia, hyperlactatemia, hypomagnesemia, hypokalemia, hypocalcemia, and hypophosphatemia. Generally, patients presenting with intoxication should be tested with a rapid bedside glucose, comprehensive urine toxicology screen, serum alcohol level, and metabolic panel. Patients with altered mental status require evaluation to rule out other serious conditions such as head trauma, infection, or hypoxia; alcohol intoxication should be a diagnosis of exclusion for altered mental status and coma.

Treatment

Management of acute intoxication is primarily supportive. Most patients only will require observation and serial examinations. Volume may be replaced with intravenous crystalloid fluids, if needed. Patients should be assessed for occult traumas and evaluated for ingestion and withdrawal of coexisting substances. Patients with intoxication may be agitated and aggressive; if they are a danger to self or others, they may require de-escalation techniques (eg, creating a calm environment, active listening, offering choices where possible) and medications such as benzodiazepines and first-generation antipsychotics (see below) to facilitate caregiving, if respiratory rate allows. Patients may need ICU higher level of care if vital signs are abnormal (eg, hypotension, tachycardia, fever, and hypothermia), hypoxia, hypoglycemia, or the need for parenteral sedation. All patients comatose from alcohol intoxication should be treated with intravenous thiamine to prevent or treat Wernicke encephalopathy (see below).

Ingestion of other alcohols (methanol or ethylene glycol) should be suspected in patients with severe metabolic acidosis and an increased anion gap (see Poisoning, Methanol & Ethylene Glycol). Isopropyl alcohol ingestion should be considered in a patient who has the appearance of alcohol intoxication, high levels of serum ketones or acetone yet without metabolic acidosis. All alcohol poisoning is associated with an increased osmolal gap if tested relatively close to time of ingestion.

ALCOHOL WITHDRAWAL

Clinical Findings

A. Symptoms and Signs

The differential diagnosis of alcohol withdrawal includes other sedative withdrawals and other causes of delirium. Acute alcoholic hallucinosis must be differentiated from other acute paranoid states such as amphetamine psychosis or paranoid schizophrenia.

The onset of withdrawal symptoms is usually 6–36 hours, and the peak intensity of symptoms is 48–72 hours, after alcohol consumption is stopped. The wide spectrum of manifestations of alcohol withdrawal ranges from anxiety, decreased cognition and tremulousness to increasing irritability and hyperreactivity to full-blown delirium tremens (DTs).

Alcohol withdrawal syndrome can be categorized as mild, moderate, or severe withdrawal, withdrawal seizures, and DTs (Table 48–7).

In addition to the symptoms of immediate withdrawal, longer-term symptoms include sleep disturbances, anxiety, depression, excitability, fatigue, and emotional volatility. These symptoms may persist for 3–12 months, and in some cases become chronic.

B. Laboratory Tests

Laboratory testing typically includes a CBC, serum electrolytes with potassium, magnesium and calcium, bedside blood glucose test, serum creatinine, liver biochemical tests, amylase and lipase, comprehensive urine toxicology screen to rule out other co-ingested substances, and serum alcohol concentration. If there is a change from a patient's prior presentation (eg, new-onset seizure) or a change in consciousness, workup for occult trauma may include a head CT. An abdominal ultrasound may be considered for abdominal pain, or abnormal pancreatic or liver enzymes.

Complications

A. Alcoholic (Organic) Hallucinosis

This syndrome occurs either during heavy drinking or on withdrawal and is characterized by a paranoid psychosis without the tremulousness, confusion, and clouded sensorium seen in withdrawal syndromes. The patient appears normal except for the auditory hallucinations, which are frequently persecutory and may cause the patient to behave aggressively and in a paranoid fashion.

B. Chronic Alcoholic Brain Syndromes

These encephalopathies are characterized by increasing erratic behavior, memory and recall problems, and

Table 48–7. Categories and presentations of alcohol withdrawal syndromes.

Category	Symptoms and Complications	Onset and Duration	Comment
Mild	**Symptoms:** Tremor, anxiety, tachycardia, nausea, vomiting, and insomnia	Within 6 hours after the last drink, often before the blood alcohol levels drop to zero Usually subside by day 2	
Moderate	Symptoms and signs fall between those of minor and major withdrawal.		
Severe or major withdrawal	**Symptoms:** Disorientation, agitation, diaphoresis, whole body tremor, vomiting, hypertension, and hallucinations (visual more often than tactile, which is more often than auditory)	48–96 hours after the last drink	Usually preceded by prolonged heavy alcohol use
Withdrawal seizures (generalized non-focal tonic-clonic)	**Symptoms:** Brief and resolve spontaneously More prevalent in persons who have a history of withdrawal syndromes	8 hours after the last drink but usually do not manifest > 48 hours after alcohol cessation	If left untreated, can recur in about 60% of patients
Delirium tremor (DT)	**Symptoms:** Extreme mental confusion, agitation, tremor, diaphoresis, sensory hyperacuity, visual hallucinations (often of snakes, bugs, etc), and autonomic hyperactivity (tachycardia and hypertension) **Complications (partial list):** Dehydration, electrolyte disturbances (hypokalemia, hypomagnesemia), arrhythmias and seizures, and even cardiovascular collapse and death	48–72 hours after the last drink but may occur up to 7–10 days later	Most severe form of alcohol withdrawal Develops in about 50% of patients who have had withdrawal seizures, but can develop in the absence of seizures When the patient has been hospitalized for an unrelated problem, the acute withdrawal syndrome is often unexpected, thus presenting as a diagnostic dilemma. Alcohol withdrawal should be suspected in every patient with unexplained delirium. Mortality rate has steadily decreased with early diagnosis and improved treatment

emotional instability—the usual signs of organic brain injury due to any cause. Wernicke-Korsakoff syndrome due to thiamine deficiency may develop with a series of episodes. **Wernicke encephalopathy** consists of the triad of confusion, ataxia, and ophthalmoplegia (typically sixth nerve palsy). Early recognition and treatment with thiamine can minimize damage. One of the possible sequelae is **Korsakoff psychosis**, characterized by both anterograde and retrograde amnesia, with confabulation early in the course. Early recognition and treatment with intravenous thiamine and B complex vitamins can minimize damage.

Treatment

Benzodiazepines (specifically diazepam) are the only proven method to prevent delirium tremens, however they also increase the risk of delirium. Long-acting benzodiazepines with active metabolites (such as diazepam or chlordiazepoxide) are preferred. For patients with advanced cirrhosis or acute alcohol-related hepatitis, lorazepam or oxazepam is preferred as the shorter half-life (lorazepam) and absence of active metabolizes (oxazepam) reduce risk if oversedation occurs. For this reason, chlordiazepoxide is avoided for patients with advanced cirrhosis due to the long half-life. Benzodiazepines can be administered via a fixed dose at fixed intervals regardless of Clinical Institute Withdrawal Assessment for Alcohol, Revised (CIWA-Ar) scores, or a “symptom-triggered” approach where they are administered only at CIWA scores above a certain cut-off, most commonly above 8–10 (see CIWA-Ar, below). A small nonrandomized trail suggested that symptoms-triggered protocols were associated with lower readmission rates and reduced total dose of benzodiazepines, but with longer lengths of hospital stay. Phenobarbital, a barbiturate with similar properties to benzodiazepines but with a far longer half-life, has also been studied and is the treatment of choice in some institutions.

A. Assessing the Patient for Outpatient or Inpatient Treatment

All patients should be evaluated for their risk of complicated alcohol withdrawal with tools such as the Prediction of Alcohol Withdrawal Severity Scale (PAWSS) score (https://www.mdcalc.com/calc/10102/prediction-alcohol-withdrawal-severity-scale). While the PAWSS score was developed for use in the Emergency Department setting, it can be a useful decision point in the outpatient setting. For patients with low risk of withdrawal (PAWSS <4), outpatient management is appropriate, with strict return precautions to the emergency department for worsening symptoms despite treatment. Reasons to escalate to inpatient level of care include active or worsening medical or psychiatric conditions, history of benzodiazepine use disorder, worsening withdrawal symptoms despite multiple doses of medication and the patient will not be monitored (eg, treatment setting is closing), patient appears oversedated, unstable vital signs or syncope, or a history of severe withdrawal within the past year.

B. Outpatient Management of Withdrawal

In the outpatient setting, first-line treatment options include oral benzodiazepines such as chlordiazepoxide 25–50 mg as a single dose for mild withdrawal (CIWA-Ar < 10) or 50–100 mg as a single dose for moderate withdrawal (CIWA-Ar 10-18), or diazepam 10–20 mg every 6–12 hours for the first 24 hour then reduced to 5 mg every 6–12 hours for the next 3–5 days. Non-benzodiazepine oral monotherapy includes gabapentin 1200 mg daily for days 1–3, then 300–600 mg daily for days 4–7 with additional doses as needed; or carbamazepine 600–800 mg daily tapered to 200–400 mg daily over 4–9 days.

C. Inpatient Management of Withdrawal

1. General management—When the history or presentation suggests that patients are actively in withdrawal or at significant risk for withdrawal, they should be hospitalized. Risk factors for complex withdrawal include a recent drinking history; frequent alcohol consumption; prior withdrawal, seizures, hallucinosis, or DTs; a history of needing medication for detoxification; or a history of benzodiazepine or barbiturate use, abuse, or dependency.

For all hospitalized patients, general management includes ensuring adequate hydration, correction of electrolyte imbalances (particularly magnesium, calcium, and potassium), and administering the vitamins thiamine (100 mg intravenously daily for 3 days then orally daily for prevention), folic acid (1 mg orally daily), and a multivitamin orally daily. Thiamine should be given *prior* to any glucose-containing solutions to decrease the risk of precipitating Wernicke encephalopathy or Korsakoff syndrome. Providers should have a high index of suspicion for Wernicke encephalopathy if a patient exhibits any two of four Caine criteria: (1) malnourishment (eg, recent weight loss, peripheral neuropathy), (2) extra-ocular muscle movement abnormalities, (3) impaired gait, or (4) altered mental status, and should proceed with empiric Wernicke encephalopathy treatment (thiamine 500 mg intravenously three times daily for 3–5 days).

2. Assessing symptom severity—The severity of withdrawal will determine the patient's need for inpatient or intensive care. For those at risk for withdrawal and with mild withdrawal symptoms, admission to a medical unit is adequate. For those with moderate withdrawal, a higher acuity hospital environment is recommended. Those with severe withdrawal should be admitted to the ICU.

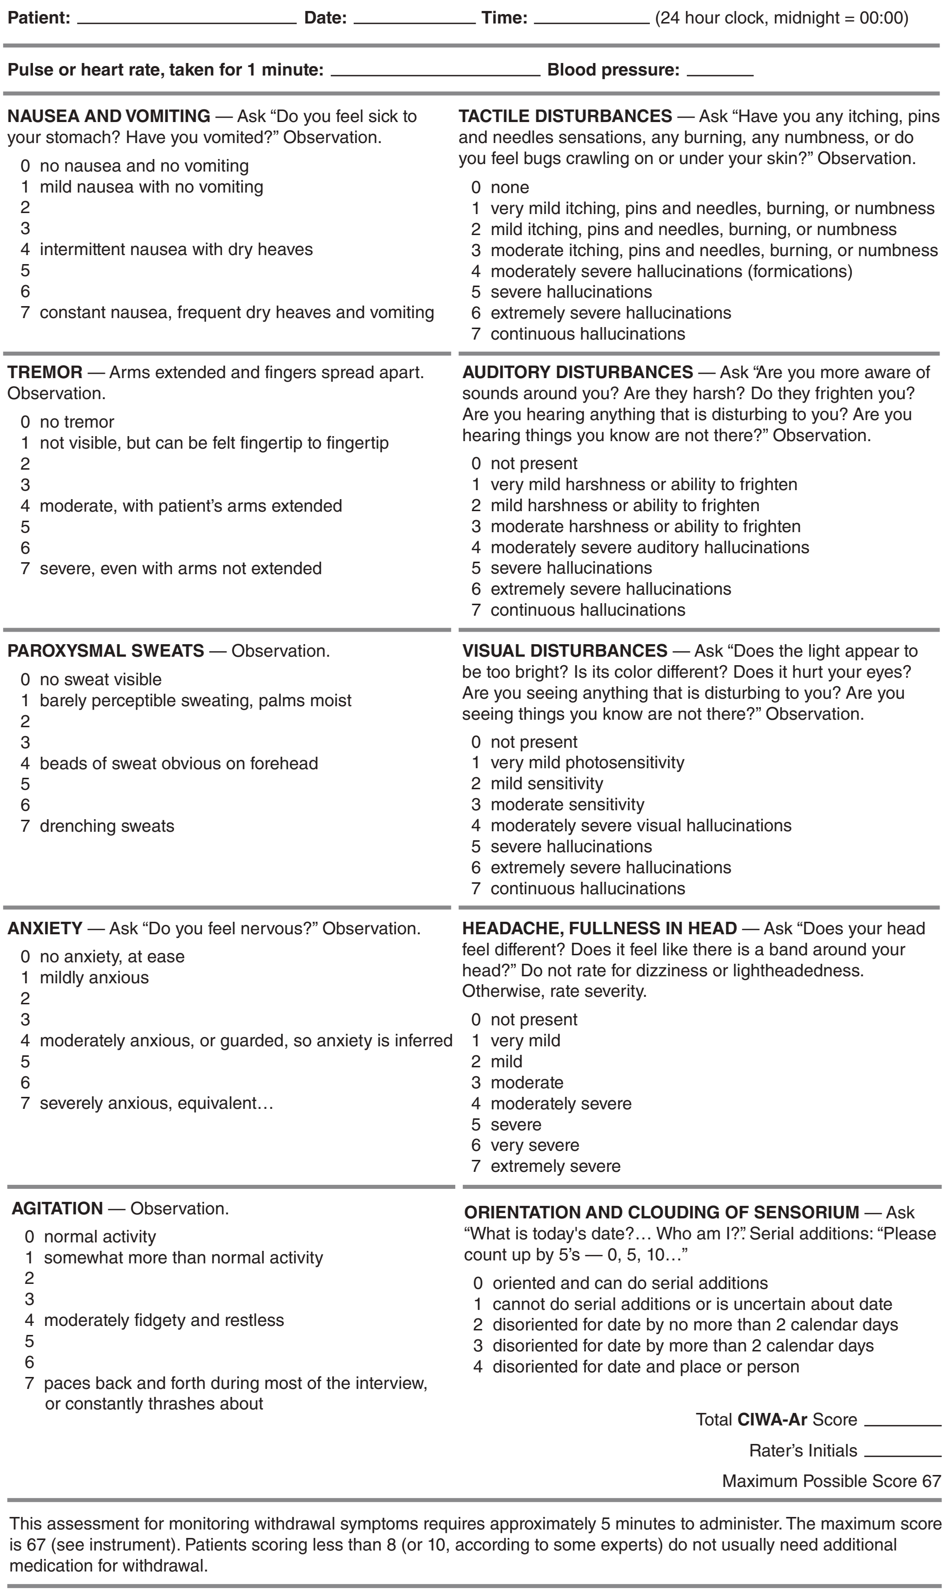
The **Clinical Institute Withdrawal Assessment for Alcohol, Revised (CIWA-Ar)** is a validated tool that is widely used to determine severity of alcohol withdrawal. This survey assesses symptoms in 10 areas (both patient-reported and observable) and can be administered relatively quickly (Figure 48–1). One caveat is that patients must be able to communicate their symptoms to the provider. The maximum attainable score is 67. Clinical judgment should be used to determine final medication dosing, as dosing will vary between patients and degrees of withdrawal.

3. Inpatient treatment of alcohol withdrawal symptoms—Alcohol withdrawal is most commonly treated with benzodiazepines. Studies of other treatment agents, such as phenobarbital and ketamine, have not demonstrated superiority to benzodiazepines. Continual assessment is recommended to determine the severity of withdrawal. Symptom-driven medication regimens are shown to prevent under- and oversedation and to reduce total benzodiazepine usage over fixed-dose schedules. Benzodiazepine-sparing order sets have successfully decreased usage of benzodiazepines through use of adjuncts such as gabapentin, valproic acid, clonidine, and dexmedetomidine.

4. Treating alcohol withdrawal symptoms based on CIWA-Ar score—

a. Minimal withdrawal symptoms (CIWA-Ar score < 8)—Patients who have a history of alcohol withdrawal with minimal withdrawal symptoms are suitable for withdrawal prophylaxis. The recommended benzodiazepine options include chlordiazepoxide or lorazepam orally, tapered over 3 days. The protocol calls for nursing assessment of sedation and withdrawal symptoms (CIWA-Ar) every 6 hours. If prophylactic medication is indicated, a sample tapering regimen may include lorazepam, 1 mg orally every 6 hours for 1 day, then 1 mg orally every 8 hours for 1 day, then 1 mg orally every 12 hours for 1 day, then discontinue; or chlordiazepoxide, 50 mg orally every 6 hours for 1 day, 25 mg orally every 6 hours for 2 days, then discontinue. Avoid chlordiazepoxide in older patients or in patients with liver disease. Lorazepam is preferred in patients with liver disease. Sedation is assessed 30–60 minutes after each medication dose. The benzodiazepine dose is held for oversedation or if the respiratory rate is < 10 breaths per minute. For CIWA-Ar score > 8, the provider must be notified, because this is suggestive of active withdrawal, and escalation of treatment must occur.

b. Mild withdrawal symptoms (CIWA-Ar score 8–15)—For patients in mild withdrawal, either chlordiazepoxide orally or lorazepam orally or intravenously can be used. Initially, chlordiazepoxide 50 mg orally or lorazepam 1 or 2 mg orally or intravenously is given hourly for 2 hours. Patients must be assessed for level of sedation and withdrawal symptoms (CIWA-Ar) every 4 hours. Dosing is



Patient: ____________ **Date:** ________ **Time:** ________ (24 hour clock, midnight = 00:00)

Pulse or heart rate, taken for 1 minute: ____________ **Blood pressure:** ______

NAUSEA AND VOMITING — Ask "Do you feel sick to your stomach? Have you vomited?" Observation.

0 no nausea and no vomiting
1 mild nausea with no vomiting
2
3
4 intermittent nausea with dry heaves
5
6
7 constant nausea, frequent dry heaves and vomiting

TACTILE DISTURBANCES — Ask "Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" Observation.

0 none
1 very mild itching, pins and needles, burning, or numbness
2 mild itching, pins and needles, burning, or numbness
3 moderate itching, pins and needles, burning, or numbness
4 moderately severe hallucinations (formications)
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

TREMOR — Arms extended and fingers spread apart. Observation.

0 no tremor
1 not visible, but can be felt fingertip to fingertip
2
3
4 moderate, with patient's arms extended
5
6
7 severe, even with arms not extended

AUDITORY DISTURBANCES — Ask "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?" Observation.

0 not present
1 very mild harshness or ability to frighten
2 mild harshness or ability to frighten
3 moderate harshness or ability to frighten
4 moderately severe auditory hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

PAROXYSMAL SWEATS — Observation.

0 no sweat visible
1 barely perceptible sweating, palms moist
2
3
4 beads of sweat obvious on forehead
5
6
7 drenching sweats

VISUAL DISTURBANCES — Ask "Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?" Observation.

0 not present
1 very mild photosensitivity
2 mild sensitivity
3 moderate sensitivity
4 moderately severe visual hallucinations
5 severe hallucinations
6 extremely severe hallucinations
7 continuous hallucinations

ANXIETY — Ask "Do you feel nervous?" Observation.

0 no anxiety, at ease
1 mildly anxious
2
3
4 moderately anxious, or guarded, so anxiety is inferred
5
6
7 severely anxious, equivalent…

HEADACHE, FULLNESS IN HEAD — Ask "Does your head feel different? Does it feel like there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity.

0 not present
1 very mild
2 mild
3 moderate
4 moderately severe
5 severe
6 very severe
7 extremely severe

AGITATION — Observation.

0 normal activity
1 somewhat more than normal activity
2
3
4 moderately fidgety and restless
5
6
7 paces back and forth during most of the interview, or constantly thrashes about

ORIENTATION AND CLOUDING OF SENSORIUM — Ask "What is today's date?… Who am I?". Serial additions: "Please count up by 5's — 0, 5, 10…"

0 oriented and can do serial additions
1 cannot do serial additions or is uncertain about date
2 disoriented for date by no more than 2 calendar days
3 disoriented for date by more than 2 calendar days
4 disoriented for date and place or person

Total **CIWA-Ar** Score ______
Rater's Initials ______
Maximum Possible Score 67

This assessment for monitoring withdrawal symptoms requires approximately 5 minutes to administer. The maximum score is 67 (see instrument). Patients scoring less than 8 (or 10, according to some experts) do not usually need additional medication for withdrawal.

Figure 48–1. Alcohol withdrawal assessment. (Reproduced from Sullivan JT et al. Assessment of alcohol withdrawal: The revised clinical institute withdrawal assessment for alcohol scale [CIWA-Ar]. Br J Addict. 1989;84:1353. This scale is not copyrighted and may be used freely.)

adjusted as necessary to control symptoms without excessive sedation. After the first 2 hours, chlordiazepoxide or lorazepam is given every 4 hours and as needed. Typical dosing may include chlordiazepoxide 25–50 mg orally or lorazepam 0.5–1 mg orally or intravenously every 4 hours as needed. Additional doses of benzodiazepines should be given if the CIWA-Ar score remains between 8 and 15.

c. Moderate withdrawal (CIWA-Ar score 16–20)— For patients in moderate withdrawal, chlordiazepoxide 100 mg orally or lorazepam 3 or 4 mg orally or intravenously is given every hour for the first 2 hours. CIWA-Ar monitoring should occur every 2 hours. Dosing is adjusted to control symptoms without excessive sedation. After initial dosing, continued treatment could include chlordiazepoxide 50 mg orally or lorazepam 1–2 mg orally or intravenously every 2 hours as needed for CIWA-Ar score between 16 and 20, and chlordiazepoxide 25 mg orally or lorazepam 0.5–1 mg orally or intravenously every 2 hours for CIWA-Ar score between 8 and 15. The maximum dose of chlordiazepoxide is 600 mg in 24 hours. Patients should be monitored with continuous pulse oximetry and cardiac monitoring. The degree of sedation should be monitored 30–60 minutes after each oral dose of medication and for 15 minutes after each parenteral dose.

d. Severe withdrawal (CIWA-Ar score > 20)—Patients with severe withdrawal are at risk for the development of DTs and should be admitted to the ICU. Intravenous lorazepam can be used to treat severe withdrawal. A potential treatment protocol is to administer lorazepam 1–2 mg intravenously every 15 minutes until the patient is calm and sedated but awake. Initial CIWA-Ar monitoring should occur every 30 minutes. The patient can then receive lorazepam 2 mg orally or intravenously every hour as needed when the CIWA-Ar score is between 16 and 20, and lorazepam 1–2 mg orally or intravenously every hour as needed when the CIWA-Ar score is between 8 and 15. If the patient requires > 8 mg/hour of lorazepam as an initial dose or continues to demonstrate observable agitation, tremors, tachycardia, or hypertension despite high doses of lorazepam, consider adding dexmedetomidine, an α_2-agonist that produces sedation with minimal effect on respiratory drive. Dexmedetomidine is not recommended as a sole agent for the treatment of alcohol withdrawal but as an adjunctive therapy (along with benzodiazepines) to decrease the hyperadrenergic output in patients with severe alcohol withdrawal not controlled by benzodiazepines or in patients at risk for respiratory depression from high-dose benzodiazepine administration. The recommended dosing of dexmedetomidine is 0.2–0.7 mcg/kg/hour, with lorazepam 1–2 mg intravenously every 8 hours plus lorazepam 1–2 mg intravenously every hour as needed for agitation. In limited cases of severe withdrawal requiring frequent lorazepam boluses for at least 6 hours, continuous intravenous lorazepam infusion can be considered, but the patient must be monitored extremely carefully for signs of respiratory depression. Continuous pulse oximetry and close observance of the patient's respiratory status are required. Sedation is assessed 15 minutes after each intravenous dose. If withdrawal symptoms are refractory to escalating benzodiazepine usage, despite the addition of dexmedetomidine, adding phenobarbital or escalation to propofol should be considered. Patients receiving large doses of benzodiazepines often require intubation for airway protection, at which time initiation of propofol infusion for sedation, in addition to treatment of refractory alcohol withdrawal, is recommended. Phenobarbital monotherapy for alcohol withdrawal is used at some institutions, but sufficiently powered RCTs comparing the efficacy of phenobarbital to benzodiazepines are needed to inform adoption of new treatment regimens.

In all cases, benzodiazepines should be held if the patient is too sedated or has a respiratory rate < 10 breaths per minute. Do not bolus lorazepam in doses > 4 mg intravenously. Mixing benzodiazepines, eg, chlordiazepoxide orally every 8 hours with lorazepam, is not recommended. Instead, select a single agent and titrate as needed. Once a patient has been stable for 24 hours, the benzodiazepine dose can be reduced by 20% daily until withdrawal is complete.

Since the symptoms are primarily those of psychosis in the presence of a clear sensorium, they are handled like any other psychosis: hospitalization (when indicated) and adequate amounts of antipsychotic medications.

5. Managing other withdrawal-associated conditions— Meticulous examination for other medical problems is necessary. Alcoholic hypoglycemia can occur with low blood alcohol levels (see Chapter 32). Patients with severe AUD commonly have liver disease with associated clotting disorders and are also prone to injury—and the combination all too frequently leads to undiagnosed subdural hematoma.

Phenytoin does *not* appear to be useful in managing alcohol withdrawal seizures. Sedating doses of benzodiazepines are effective in treating alcohol withdrawal seizures. Thus, other anticonvulsants are not usually needed unless there is a preexisting seizure disorder.

Chronic brain syndromes secondary to a long history of alcohol intake are not clearly responsive to thiamine and vitamin replenishment. Attention to the social and environmental care for this type of patient is paramount.

6. Initiating psychological and social measures—Psychological and behavioral treatment become the primary considerations after successful treatment of alcoholic hallucinosis or withdrawal. Psychological and social measures should be initiated in the hospital prior to discharge. This increases the possibility of continued posthospitalization treatment.

STIMULANTS: AMPHETAMINES & COCAINE

ESSENTIALS OF DIAGNOSIS

- Overdose death with synthetic opioids and stimulants is increasingly common.
- Stimulant use can be associated with irreversible neuropsychiatric and cardiovascular sequelae.
- Contingency management is a behavioral treatment using rewards for abstinence and is highly effective treatment.

General Considerations

Commonly used stimulants include cocaine (in base form referred to as "crack"), methamphetamine ("speed" or "crystal"), and prescription stimulants (eg, Adderrall®, or dextroamphetamine/amphetamine, or Adderrall®; methlyphenidate, or Ritalin). National household surveys (NSDUH) of non-institutionalized populations indicate that in the past year, 5 million adults have used cocaine, 3.9 million have used prescription stimulants, and 2.6 million have used methamphetamine. Prevalence of stimulant use disorder (cocaine or methamphetamine) is low and estimated at 0.5% of Americans. Cocaine and prescription stimulant use is more common among persons 18–25 years old, while methamphetamine use predominates in those 26 or older. Geographically, methamphetamine use is concentrated in the Western half of the United States, and risk factors for use include lower educational attainment, lower income, housing instability, criminal justice involvement, lack of insurance, comorbidities (eg, HIV, depression), and polysubstance use.

With illicit fentanyl and its analogs being the dominant opioid that is consumed, co-use of stimulants is common. Overdose death involving psychostimulants and opioids have increased 50-fold compared to 2010, now comprising 32% of deaths from overdose. This has been termed the "fourth-wave" of overdose death in the United States. This unprecedented rise has revealed the need to rapidly improve and expand our treatments for stimulant use disorder. There is ongoing study to determine if individuals intentionally combine opioids and stimulants or primarily use stimulants and have unintended exposure to fentanyl (eg, drug contamination). The diagnosis of a stimulant use disorder is made using *DSM-5* criteria (Table 48–1). Stimulants can be consumed by inhalation, intravenously, intramuscularly, intranasally, orally, or per rectum (eg, chemsex among men who have sex with men). Individuals may have a pattern of episodic, recreational use, and not progress to a use disorder. Alternatively, behavior dysregulation with cravings, tolerance, and potential withdrawal may develop in patients; stimulants will be used despite consequences of compulsiveness and loss of control over behavior.

Clinical Findings

A. Symptoms and Signs

Acute intoxication syndromes with stimulants are common in patients who come to emergency departments. Stimulants exert powerful effects on the cardiovascular and neuropsychiatric systems. Patients may have classic sympathomimetic overdose syndromes, including sweating, tachycardia, hypertension, mydriasis, psychomotor agitation, and/or an acute brain syndrome with confusion and disorientation. Patients may also have acute cardiac syndromes, pulmonary hypertension, arrhythmias or cardiac arrest, stroke or TIAs, seizure, or acute psychosis. Methamphetamine is associated with psychosis, impacting 36% of patients who misuse the substance. Patients exhibit prominent delusions of persecution, ideas of reference, and hallucinations that may be auditory, tactile, or visual. Stimulant use may also be present in patients with accidents or injuries, unintentional overdose, and suicide or homicide events. Acute obstetric complications from stimulant use include spontaneous abortion, abruptio placentae, teratogenic effects, delayed fetal growth, and prematurity.

Chronic intoxication, or long-term use of stimulants, can have innumerable deleterious effects on the cardiovascular and neuropsychiatric systems. Stimulants exacerbate chronic illnesses such as hypertension, CAD, and atrial fibrillation. Stimulant-associated cardiomyopathy is a complication of long-term stimulant use, especially methamphetamine, and patients show high hospitalization rates and premature mortality. Long-term use of stimulants can cause neurocognitive impairment in the domains of executive function, memory, and planning. Longitudinal studies in Thailand of patients admitted for stimulant-induced psychosis suggest that even after abstaining, up to 38% of patients will have ongoing psychiatric disease. Chronic use of stimulants has several oral and skin manifestations, including dental caries and decay from decreased salivation and bruxism; ulceration and ischemia of the nasal turbinates; excoriation and ulcers from compulsive skin picking, particularly with delusional parasitosis which can cause significant psychological distress. Chorea or choreoathetosis (purposeless, irregular, and involuntary movements in the trunk and extremities) is a rare but striking complication. This syndrome typically resolves after cessation of use.

Sudden withdrawal of the drug is not life-threatening but usually produces craving, sleep disturbances, hyperphagia, lassitude, and severe depression (sometimes with suicidal ideation) lasting days to weeks.

B. Laboratory Tests

Immunoassays of urine samples to detect stimulant use are widely available. The cocaine immunoassay has high sensitivity and specificity, but the amphetamine assay has a high risk of false positive results (4–10%), with the following drugs commonly producing false positive results: trazodone, promethazine, bupropion, and labetalol (among others). It is recommended that a positive amphetamine screen be confirmed by gas chromatography mass spectrometry testing. Taking a medication review and checking a prescription activity report is also important for any positive test as the person may have had it prescribed (eg, mixed amphetamine salts or Adderall®). Other laboratory tests include a CBC, liver enzymes, glucose, electrolytes and kidney function, and markers of muscle breakdown (eg, CK) or cardiac injury (eg, troponin). HIV, STIs, and hepatitis screening is recommended. Cardiovascular risk assessment should be performed for patients with simulant use disorder via online calculators such as PREVENT, which includes cholesterol, GFR, and HbA_{1c}.

Complications

Hyperadrenergic syndromes from stimulant use can cause rhabdomyolysis and acute kidney injury. Other medical complications include levamisole-related small vessel vasculitis in persons using cocaine or crack. Patients may have skin ulcerations (retiform purpura), including the nose and ear pinna, plus neutropenia and abnormal ANA and p-ANCA (anti-MPO) testing. In patients with HIV, active stimulant use is a risk for a nonsuppressed viral load and HIV progression. Clinicians should be alert to possible stimulant use in patients with unexplained nasal bleeding or septal perforations, headaches, fatigue, insomnia, anxiety, depression, and chronic hoarseness.

Treatment

Treatment of acute intoxication syndromes is supportive and targets the dominant symptom while aiming to prevent end-organ damage. Acute agitation and paranoia may require use of sedatives (eg, benzodiazepines) and antipsychotics. Haloperidol, quetiapine, risperidone, aripiprazole, and olanzapine are effective at clinically relevant doses in stimulant-induced psychosis (Table 28–3). Sympathomimetic overdose syndromes may require cooling if hyperthermic, fluid resuscitation, and treatment of hypertension. Of note, the common teaching to avoid β-blockers in stimulant-induced chest pain due to unopposed α activity and vasoconstriction has been reconsidered. Numerous studies show that there is no conclusive evidence that unopposed α stimulation regularly occurs or that it predictably causes adverse outcomes. β-Blockers can be highly effective treatments to aid with acute blood pressure and pulse lowering.

Treatment of stimulant withdrawal is supportive and may include medication to address symptoms such as sleep abnormalities and depressed mood.

Chronic treatment of stimulant use disorder can be behavioral or medical. The best behavioral treatment for stimulant use disorders recommended by the ASAM is contingency management. Contingency management uses operant conditioning, such that the patient gets a reward in response to doing a target behavior (eg, not using the drug), and if the reward is sufficiently large or salient, the target behavior continues. Contingency management programs are cost-effective, and increasingly available in some outpatient addiction programs, general medicine settings, or through online platforms, though broad access is still lacking. Other evidence-based behavioral treatments include cognitive behavioral therapy and the Matrix Model (a type of intensive outpatient treatment). Fellowship groups exist specifically for stimulants, including Crystal Meth Anonymous and Cocaine Anonymous. Harm reduction counseling should be provided to all patients, including offers of naloxone for any person at risk of unintentional overdose.

There are no FDA approved medications for treatment of stimulant use disorders. Off-label use of bupropion, bupropion and extended-release naltrexone, topiramate, or mirtazapine have been shown to decrease the frequency of methamphetamine use and are often trialed if the patient has a co-occurring disorder that also might benefit from the medication (eg, nicotine use disorder for bupropion). Modafinil or topiramate may be considered for cocaine use disorder.

CANNABIS & CANNABINOIDS

ESSENTIALS OF DIAGNOSIS

- Cannabis use disorder (CUD) is the second most common SUD after AUD in the United States.
- Cannabis is a federal schedule I illegal substance; state laws, however, shape legality of recreational or medicinal use and are the regulations most enforced.
- There are no FDA approved medications to treat CUD, however behavioral based treatments can be effective.

General Considerations

Cannabis is an umbrella term used to describe products such as cannabinoids, marijuana, and hemp derived from the *Cannabis sativa* plant. Cannabis activates endogenous brain cannabinoid (CB) receptors (CB1 receptors in the endocannabinoid system) and in other organs (such as CB2 receptors in the immune system). Cannabis has medicinal and non-medicinal use, and CUD is the most common type of SUD (6.8%) after AUD. Cannabis is classified federally as a schedule I drug due to its addictive potential so it cannot be prescribed. However, most states have legalized medical use of cannabis and federal law is generally not enforced in those states. Medicines with extracted or synthesized cannabinoids have shown small to modest benefits in treating chronic pain, muscle spasticity, chemotherapy-induced nausea and vomiting, and refractory epilepsy (specifically CBD). With increasing legalization, the number of regular users who have used higher potency cannabis for medicinal or recreational purposes has risen. The most common routes of use are inhalation (via various modalities: pipe, rolled, or "vaping," etc.) or oral (ie, "edibles"). Over time, all cannabis formulations have become stronger, and delivery methods have been developed to further increase potency, such as vaping.

Synthetic cannabinoids (such as "K2", "Spice") have much higher potency and are associated with death, tachycardia, and seizures thought due to their higher toxicity and longer lasting effects. Adolescents are particularly impacted by cannabis, with use reported among 16.6%, and long-term complications of use including cognitive impairment, dependence and reduced educational attainment.

Clinical Findings

The diagnosis of CUD is made using the *DSM-5* criteria and is characterized by use despite consequences.

A. Symptoms and Signs

1. Intoxication—The intoxication syndrome produces two phases: mild euphoria followed by sleepiness. In the acute state, the user has an altered time perception, less inhibited emotions, psychomotor problems, impaired immediate memory, and conjunctival injection. High doses produce transient psychotomimetic effects. Peak onset of action is reached within 3–10 minutes for inhaled cannabis versus 1–6 hours for oral formulations, which can have a half-life of 20–30 hours. Cannabis use frequently aggravates existing mental illness and adversely affects motor performance.

2. Withdrawal—Withdrawal produces insomnia, nausea, myalgia, and irritability. Cannabis withdrawal typically starts within 1–2 days after cessation, symptoms peak at 2–6 days and can take up to 3 weeks to resolve in more frequent cannabis users.

B. Laboratory Tests

THC can be detected in the urine up to 3 days after last use in most individuals, particularly with long-term use. THC is absorbed in fat and can be eliminated over a longer time period. In one small high-quality study, the urine of individuals with consistent use of high potency cannabis was positive for THC up to 24 days. In contrast, regular use of low dose THC containing hemp oil has not been shown to result in urine positive for THC. Almost all synthetic cannabinoids (other than "HU-210") do not cross react with THC immunoassays and are not included in confirmatory liquid chromatography–mass spectrometry testing; synthetic cannabinoids, therefore, do not appear on these urine drug tests.

Complications

Cannabis use can have significant medical complications. Acute use can be associated with cognitive impairment and acute psychosis, cardiac arrhythmias and car accidents, while long term use has been shown to worsen or increase the risk of serious mental illness including psychosis as well as cognition in addition to other medical complications. Prolonged use can also be associated with developing CUD.

1. Acute intoxication—Cognitive impairments are common, including impaired verbal memory, increased disinhibition, reduced attention, and psychomotor disfunction that may recover within hours or days but can be prolonged with chronic use. Studies have shown that this reduced cognitive function may take up to 2–25 days to resolve with abstinence. Acute cannabis-associated psychotic symptoms can occur at rates of nearly 0.5% for lifetime occurrence and can manifest as hallucinations requiring emergency department level care. Cardiovascular complications include arrhythmias with acute use, and consistent evidence of cardiovascular events with chronic and acute intoxication. From a public health perspective, acute cannabis consumption has been associated with a modest increase in traffic accidents (OR 1.25–1.97) that occurs most frequently 5–6 hours after use and is exacerbated with concomitant alcohol use when driving.

2. Long-term use—While many individuals use cannabis regularly to treat mood or anxiety disorders, regular use has been associated with increased risk of major depression (two-fold for misuse and 3–5 times for those with CUD) and anxiety (two-fold for misuse, 3–4 times higher in those with CUD). Frequent cannabis use is associated with bipolar disorder (and greater symptom severity) and increased risk of psychosis (five-fold with daily use of high potency cannabis compared to non-users), versus a two-fold increased risk among daily users of low potency cannabis. Notably, infrequent use (less than once per week) was not associated with a psychotic disorder. Daily cannabis use is associated with MI and stroke, with increased use frequency associated with higher odds (25 and 42%, respectively).

3. Cannabis use disorder—The diagnosis is made using the *DSM-5* criteria, similar to the other substance use disorders. CUD is characterized by repeated use despite harm and is the second most common SUD in the United States. Worldwide, rates of CUD are near those of OUD. Risks of developing CUD for those with chronic use are 22% (ever use) versus 33% (daily use), and risk factors are male gender, younger age, and high potency cannabis.

4. Hyperemesis syndrome—This syndrome is a unique complication categorized by cyclic episodes of nausea, vomiting and intense abdominal pain that occur with prolonged high potency cannabis use, and is relieved by hot baths, showers, capsaicin cream, and abstinence from cannabis.

5. Other symptoms—Pulmonary complications are well established, including non-specific symptoms such as cough, as well as specific pulmonary injury due to contaminants ("e-cigarette" or vaping product use associated lung injury "EVALI"). Fertility of all genders can be impacted, where long-term usage has resulted in depression of plasma testosterone levels and reduced sperm counts, and abnormal menstruation and failure to ovulate. The intelligence quotient has been shown to decrease by 2 points per year after the start of frequent or dependent use of cannabis, and early onset of cannabis (< 25 years old) for those with frequent use are associated with lower educational achievement including early school drop-out and fewer academic degrees. In pregnant persons, regular cannabis use increases the risk of maternal anemia and neonatal complications such as neonatal ICU stay and reduced birth weight.

Treatment

There is no specific pharmacologic treatment for intoxication, withdrawal, or ongoing CUD. For the acute intoxication phase, no specific treatment is necessary other than addressing acute complications as noted above. Cannabis withdrawal does not typically require hospitalization; however, for those with significant comorbid health disorders and with concurrent other substance use, inpatient management may be indicated. For CUD, motivational interviewing, cognitive behavioral therapy, and contingency management result in greater reductions in cannabis use.

Hoch E et al. Cannabis, cannabinoids and health: a review of evidence on risks and medical benefits. Eur Arch Psychiatry Clin Neurosci. 2025;275:281. [PMID: 39299947]

OTHER DRUG & SUBSTANCES

1. Psychedelics

Classic psychedelics include the semi-synthetic lysergic acid diethylamide (LSD) derived from the ergot fungus, mescaline, psilocybin, dimethyltryptamine (DMT), and other derivatives of phenylalanine and tryptophan, many of which have been used in myriad traditional sacramental and healing contexts worldwide. It has been shown that lifetime classic psychedelic use has a prevalence of 13.6% in the US adult population. In contrast to most drug use, lifetime use of classic psychedelics has been found to significantly reduce odds of past month psychological distress, past year suicidal thinking, past year suicidal planning, and past year suicide attempt. A group of synthesized “novel psychedelics” (typically with names describing their chemical structures) remains understudied though increasingly used.

Clinical Findings

Psychedelic use can result in various responses. Generally, there is an initial feeling of tension that is followed by emotional release such as crying or laughing (1–2 hours). Later and at higher doses, perceptual distortions occur, with visual illusions and hallucinations, and occasionally there is fear of ego disintegration (2–3 hours). Major changes in time sense and mood lability then occur (3–4 hours). A feeling of detachment and a sense of destiny and control follow (4–6 hours). Occasionally, the acute episode is terrifying (a “bad trip”), which may include panic, depression, confusion, or psychotic symptoms.

The most commonly affected organ systems include cardiovascular (tachycardia), neurologic (CNS depression, seizure, coma in severe cases), and GI (nausea or vomiting). Acute complications can include serotonin toxicity, which can include myoclonus, fever, hyperthermia, tachycardia, and agitation (see Poisonings, LSD & Other Hallucinogens).

Treatment

Treatment of the acute episode primarily involves reduction of harm to the individual from erratic behavior that may lead to injury or death. A structured environment is usually sufficient until the drug is metabolized. In severe cases, antipsychotic medications with minimal side effects (eg, haloperidol, 5 mg intramuscularly) may be given every several hours until the individual has regained control. In cases where “flashbacks” occur (mental imagery from a “bad trip” that is later triggered by mild stimuli such as marijuana, alcohol, or psychic trauma), a short course of an antipsychotic medication—eg, olanzapine, 5–10 mg daily orally, or risperidone, 2 mg daily orally, initially, and up to 20 mg daily and 6 mg daily, respectively—is usually sufficient. Lorazepam or clonazepam, 1–2 mg orally every 2 hours as needed for acute agitation, may be a useful adjunct. An occasional patient may have “flashbacks” for much longer periods and may require small doses of antipsychotic medications over the longer term.

2. Phencyclidine

Phencyclidine (PCP, angel dust, peace pill, hog) is simple to produce and mimics to some degree the traditional psychedelic drugs. PCP is a common deceptive substitute for LSD, tetrahydrocannabinol, and mescaline. It is available in crystals, capsules, and tablets to be inhaled, injected, swallowed, or smoked (it is commonly sprinkled on marijuana).

Clinical Findings

Absorption after smoking is rapid, with onset of symptoms in several minutes and peak symptoms in 15–30 minutes. Mild intoxication produces euphoria accompanied by a feeling of numbness. Moderate intoxication (5–10 mg) results in disorientation, detachment from surroundings, distortion of body image, combativeness, unusual feats of strength (partly due to its anesthetic activity), and loss of ability to integrate sensory input, especially touch and proprioception. Physical symptoms include dizziness, ataxia, dysarthria, nystagmus, retracted upper eyelid with blank stare, hyperreflexia, and tachycardia. There are increases in blood pressure, respiration, muscle tone, and urine production. Usage in the first trimester of pregnancy is associated with an increase in spontaneous abortion and congenital defects. Severe intoxication (≥ 20 mg) produces an increase in degree of moderate symptoms, with the addition of seizures, deepening coma, hypertensive crisis, and severe psychotic ideation. The drug is long-lasting (several days to several weeks) owing to high lipid solubility, gastroenteric recycling, and the production of active metabolites. Differential diagnosis involves the whole spectrum of street drugs, since in some ways phencyclidine mimics sedatives, psychedelics, and marijuana in its effects. Blood and urine testing can detect PCP use.

Overdose may be fatal, with the major causes of death being hypertensive crisis, respiratory arrest, and convulsions.

Acute rhabdomyolysis has been reported and can result in myoglobinuric kidney failure (see Poisonings, LSD & Other Hallucinogens).

▶ Treatment

GI decontamination is generally unnecessary in PCP ingestions; however, activated charcoal may be beneficial with massive ingestion of PCP or a dangerous co-ingestion if taken within one hour of ingestion. (see Poisonings, LSD & Other Hallucinogens). Treatment for agitation, violent behavior, and psychosis due to intoxication involves placing the patient in a calm and dark environment. Sedation and restraints (medication and physical) may be needed. Benzodiazepines (lorazepam 2–4 mg or diazepam 5–10 mg, both either intravenously or intramuscularly) are the preferred medication for chemical sedation. Repeated doses every 10 minutes may be required for adequate sedation. Benzodiazepines are also the first-line treatment for PCP-induced hypertension, seizures, and psychomotor agitation.

Additional treatment may include psychiatric evaluation if behavioral issues persist despite resolution of other complications. Otherwise, patients with mild symptoms can often be discharged 1 to 2 hours after symptoms resolve. Patients who present without symptoms to an emergency department after reporting PCP intake should be observed for at least 6 hours before discharge.

3. Sedatives (Anxiolytics)

See Anxiety Disorders, Chapter 28.

4. Caffeine

Caffeine is one of the most commonly used substances worldwide, with nearly 90% of adults reporting regular intake, although a caffeine use disorder is not described. Tea, cocoa, and cola drinks contribute to an intake of caffeine that is often high in many people. Low to moderate doses (30–200 mg/day) may improve some aspects of performance (eg, vigilance). The approximate content of caffeine in a (180-mL) cup of beverage is as follows: brewed coffee, 80–140 mg; instant coffee, 60–100 mg; decaffeinated coffee, 1–6 mg; black leaf tea, 30–80 mg; tea bags, 25–75 mg; instant tea, 30–60 mg; cocoa, 10–50 mg; and 12-oz cola drinks, 30–65 mg. A 2-oz chocolate candy bar has about 20 mg. Some herbal teas (eg, "morning thunder") contain caffeine. Caffeine-containing analgesics usually contain approximately 30 mg per unit and have been used to treat post-operative headaches.

Symptoms of caffeinism (usually associated with ingestion > 500 mg daily) include anxiety, agitation, restlessness, insomnia, a feeling of being "wired," and somatic symptoms referable to the heart and GI tract. It is common for caffeinism to present as an anxiety disorder. It is also common for caffeine and other stimulants to precipitate severe symptoms in patients with compensated schizophrenia and manic-depression. Patients who are chronically depressed often use caffeine drinks as self-medication.

Caffeine intoxication from caffeine doses of 1 g (15 mg/kg) includes symptoms of tachycardia, insomnia, agitation, tachypnea, psychomotor agitation, GI irritation, and anxiety. Although rare, excessive consumption of caffeine can result in death. The fatal acute oral dose of caffeine is generally considered to be 5–10 g. Ingestion of caffeine in doses ≥ 5 g can lead to vomiting, seizures, arrhythmias and MI, and death.

Caffeine withdrawal can occur after abrupt discontinuation of caffeine. The seven domains of caffeine withdrawal are drowsiness, difficulty concentrating, mood disturbances, low sociability and motivation, nausea or upset stomach, flu-like symptoms, and headache. Withdrawal may occur upon abstinence from chronic caffeine exposure at doses as low as 100 mg daily, and upon abstinence following only 3–7 days of caffeine exposure at higher doses. Caffeine withdrawal can occur in hospitalized patients who are not taking anything by mouth.

5. Miscellaneous Drugs & Solvents

MDMA/Molly/Ecstasy (3,4-methylenedioxymethamphetamine) is a synthetic drug that increases release of serotonin and dopamine, and is thus misused to increase energy, boost mood, and increase bonding with others. Complications of use include liver damage, extended depressed mood, sexual assault, hyponatremia, rhabdomyolysis, serotonin syndrome, multiorgan failure, cardiovascular events, arrhythmias, and death. Concurrent use with an SSRI can increase negative health effects. Use has been associated with panic attacks and anxiety, and chronic use can lead to insomnia, anxiety, paranoia, memory and attention problems.

Antihistaminic agents sold over the counter are frequently found in combination with a mild analgesic promoted as cold remedies. Medications containing phenylpropanolamine are banned from sale in the United States. Side effects of phenylpropanolamine relate to its effect as a stimulant, including precipitation of anxiety states, increased blood pressure effects, auditory and visual hallucinations, paranoid ideation, and occasionally delirium. Aggressiveness and some loss of impulse control were reported as well as sleep disturbances even with small doses.

Antihistamines, such as most over the counter sleep aids, usually produce some CNS depression. The mixture of antihistamines with alcohol often exacerbates the CNS effects. Scopolamine and bromides generally have been removed from over-the-counter products.

Laxative overuse can lead to electrolyte disturbances that may contribute to the manifestations of a delirium. The greatest use of laxatives tends to be in older adults and those with eating disorders, both of whom are already vulnerable to physiologic changes.

Anabolic steroid misuse includes use non-prescribed use to increase muscle mass for appearance or strength. In addition to the medical problems, the practice is sometimes associated with significant mood swings, aggressiveness, and paranoid delusions. Alcohol and stimulant use may concomitantly occur more frequently in patients who misuse anabolic steroids. Withdrawal symptoms of steroid dependency include fatigue, depressed mood, restlessness, and insomnia.

Amyl nitrite can cause effects like changes in time perception, a "rush," and mild euphoria, and it has been used to enhance orgasms. Subjective effects last from 5 seconds to 15 minutes. Tolerance develops readily, but there are no known withdrawal symptoms. Abstinence for several days reestablishes the previous level of responsiveness. Long-term effects may include damage to the immune system and respiratory difficulties.

Nitrous oxide (“N_2O,” “whippets”) has partial agonist activity at the mu, kappa, and sigma opioid receptors. Intoxication is characterized by poor oxygenation (inhalants displace oxygen with other gasses), acute asphyxia, arrhythmia and sudden death. It can cause a transient state of excitation followed by sedation, ataxia, slurred speech, cognitive impairment, and slow reactivity. At high concentrations, hallucinations and psychosis can occur. Nitrous oxide typically clears in 5 minutes. Withdrawal syndromes have not been well documented. The most commonly noted complication is functional vitamin B_{12} deficiency marked by combined degeneration of the spinal cord with difficulty ambulating, and in rare cases altered mental status with CNS involvement. Treatment is with aggressive vitamin B_{12} supplementation (1000 mcg intramuscularly daily or every other day in the first week, followed by weekly for 4–8 weeks, then monthly). Concurrent megaloblastic anemia typically resolves in 6–8 weeks.

Inhalation of solvents and gases (including aerosols) can produce a form of inebriation similar to that of volatile anesthetics. Agents include gasoline, toluene, petroleum ether, lighter fluids, cleaning fluids, paint thinners, and solvents that are present in many household products (eg, nail polish). Typical intoxication states include euphoria, slurred speech, hallucinations, and confusion, and with high doses, acute manifestations are unconsciousness and cardiorespiratory depression or failure. Chronic exposure produces a variety of symptoms related to the liver, kidney, bone marrow, or heart. Lead encephalopathy can be associated with sniffing leaded gasoline. In addition, studies of workers chronically exposed to jet fuel showed significant increases in neurasthenic symptoms, including fatigue, anxiety, mood changes, memory difficulties, and somatic complaints. These same problems have been noted in long-term solvent use.

e1-01

Penicillins

Katherine Gruenberg
Emily Kaip

The penicillins share a common chemical nucleus (6-aminopenicillanic acid) that contains a β-lactam ring essential to their biologic activity.

Antimicrobial Action & Resistance

The initial step in penicillin action is binding to receptors, ie, penicillin-binding proteins. After attaching to receptors, penicillins inhibit peptidoglycan synthesis by blocking transpeptidation. The final bactericidal action is to remove an autolytic enzyme inhibitor in the cell wall, which results in cell lysis. Organisms that produce β-lactamases (**penicillinases**) are resistant to some penicillins because the β-lactam ring is broken. Only organisms actively synthesizing peptidoglycan (in the process of multiplication) are susceptible to penicillins and other β-lactam antibiotics. Nonmultiplying organisms or those lacking cell walls are not susceptible.

Microbial resistance to penicillins is associated with five mechanisms: (1) production of β-lactamases, (eg, by staphylococci, gonococci, *Haemophilus* species, and coliform organisms, including extended-spectrum β-lactamase [ESBL]–producing bacteria); (2) lack of penicillin-binding proteins or decreased affinity of penicillin-binding protein for β-lactam antibiotic receptors (eg, resistant pneumococci, methicillin-resistant staphylococci, enterococci); (3) impermeability of the cell envelope (eg, by *Pseudomonas* species); (4) failure to activate autolytic enzymes in the cell wall—“tolerance” (eg, in staphylococci, group B streptococci); and (5) cell wall-deficient (L) forms or mycoplasmas, which do not synthesize peptidoglycans.

1. Natural Penicillins

The natural penicillins include **penicillin G** for parenteral administration (aqueous crystalline for intravenous or benzathine penicillin G for intramuscular administration) or for oral administration (penicillin G and phenoxymethyl penicillin [**penicillin V**]). *They are most active against gram-positive organisms and are susceptible to hydrolysis by β-lactamases.* They are used (1) for infections caused by susceptible and moderately susceptible pneumococci, depending at the site of infection; (2) other streptococci, such as *Streptococcus pyogenes* (including anaerobic streptococci); (3) meningococci; (4) non–β-lactamase-producing staphylococci; (5) *Treponema pallidum* and other spirochetes; (6) *Cutibacterium* (formerly *Propionibacterium*) *acnes* and other gram-positive anaerobic bacilli; (7) non-difficile clostridia; and (8) *Actinomyces*. See Table 35–5.

Pharmacokinetics & Administration

Penicillin has wide extracellular distribution with decreased levels in the eye, prostate, and CSF. However, with inflamed meninges and appropriate dosing, sufficient penetration into the CSF can be achieved.

Intramuscular administration of benzathine penicillin allows for extended-release of penicillin, providing continuous therapeutic blood and tissue levels for the treatment of syphilis.

Phenoxymethyl penicillin (penicillin V) is the oral penicillin of choice because of its superior bioavailability compared with penicillin G. Penicillin is primarily eliminated by the kidney through both glomerular filtration and active tubular secretion.

Clinical Uses

Most infections due to susceptible organisms respond to aqueous penicillin G in daily doses of 1–2 million units administered intravenously every 4–6 hours. For more serious infections (meningitis, endocarditis), increased doses (3–4 million units intravenously every 4–6 hours with normal kidney function) are required.

Penicillin V (or oral amoxicillin) is the medication of choice for the treatment of *S pyogenes* pharyngitis and cellulitis. In general, treatment of syphilis requires weekly injections of benzathine penicillin, 2.4 million units intramuscularly for 1–3 weeks, depending on the stage of the disease (see Table 35–6). Treatment of neurosyphilis, ocular syphilis, otosyphilis, or congenital syphilis requires intravenous aqueous penicillin G.

2. Extended-Spectrum Penicillins

The extended-spectrum group of penicillins includes the aminopenicillins: **ampicillin** and **amoxicillin.**

These medications are susceptible to destruction by staphylococcal (and other) β-lactamases. The ureidopenicillin **piperacillin** is available only in combination with the β-lactamase inhibitor tazobactam (**piperacillin-tazobactam**). This group of penicillins is similar to the natural penicillins in its activity against gram-positive bacteria; however, these agents offer modest aerobic gram-negative coverage as well.

Antimicrobial Activity

Ampicillin and amoxicillin are active against most strains of *Proteus mirabilis*, *Listeria*, and non–β-lactamase-producing *Haemophilus influenzae.* They are inactive against most aerobic gram-negative pathogens. Both are predictably active against penicillin-susceptible pneumococcus and *Enterococcus faecalis;* however, ampicillin-resistant *E faecalis* has emerged. *Enterococcus faecium* is commonly resistant to both ampicillin and piperacillin.

Piperacillin is active against *Pseudomonas aeruginosa* and *Klebsiella*. Piperacillin and ampicillin have approximately equal activity against *E faecalis* and pneumococci. It inhibits many, but not all, anaerobes. Unlike ampicillin and amoxicillin, piperacillin is active against β-lactamase–producing strains of *Bacteroides fragilis*.

Pharmacokinetics & Administration

Ampicillin can be administered orally or parenterally. Amoxicillin is preferable to ampicillin in the oral treatment of infection because of its improved oral bioavailability and more favorable dosing requirements. Piperacillin (in combination with tazobactam) is given intravenously, and increased doses (200–300 mg/kg/day piperacillin component) are required for treatment of infections due to *P aeruginosa.*

Clinical Uses

Amoxicillin is given orally for minor upper respiratory tract infections, such as acute sinusitis or acute otitis media and uncomplicated, outpatient community-acquired pneumonia. Ampicillin is administered intravenously for hospitalized patients with community-acquired pneumonia (in combination with sulbactam), meningitis, bacteremia, or endocarditis.

Because of the increased serum and respiratory secretion levels with amoxicillin when compared with penicillin, amoxicillin is effective in the treatment of susceptible and moderately penicillin-susceptible pneumococcus. Maintenance of amoxicillin levels above the *minimum inhibitory concentration (MIC)* of intermediately susceptible pneumococcus for > 40% of the dosing interval (which can be achieved with a dose of 40 mg/kg/day in adults) optimizes clinical and microbiologic outcomes. Amoxicillin 1 g three times daily is recommended for treatment of uncomplicated, outpatient community-acquired pneumonia. Amoxicillin is also used as prophylaxis for endocarditis in at-risk patients prior to certain dental procedures.

3. Penicillins Combined With β-Lactamase Inhibitors

The addition of β-*lactamase inhibitors* (**clavulanic acid, sulbactam, tazobactam, durlobactam**) prevents inactivation of the parent penicillin by some, but not all, β-lactamases. Marketed products include amoxicillin plus clavulanic acid, ampicillin plus sulbactam, piperacillin plus tazobactam, and sulbactam plus durlobactam. Amoxicillin-clavulanic acid is given orally; ampicillin-sulbactam, piperacillin-tazobactam, and sulbactam-durlobactam are administered intravenously. In Europe, amoxicillin-clavulanic acid is also available as a parenteral formulation. In general, the β-lactamase inhibitors effectively inactivate β-lactamases produced by *Staphylococcus aureus, H influenzae, Moraxella catarrhalis*, and *B fragilis*. Sulbactam-durlobactam is uniquely designed to target *Acinetobacter-baumannii-calcoaceticus* complex. In contrast, the β-lactamase inhibitors are variably and unpredictably effective against β-lactamases produced by certain aerobic gram-negative bacilli, such as *Enterobacter.* Of the available parenteral penicillin–β-lactamase inhibitor combinations, piperacillin-tazobactam has the broadest spectrum of activity. Like ampicillin-sulbactam, piperacillin-tazobactam is active against ampicillin-susceptible enterococci. It has greater in vitro activity against *P aeruginosa, Serratia*, and *Klebsiella* species than amoxicillin-clavulanic acid or ampicillin-sulbactam. While piperacillin-tazobactam is sometimes active in vitro against ESBL-producing organisms, its clinical efficacy is less consistent when compared with other agents. Carbapenem antibiotics (see below) should be considered the first-line treatment of serious infections due to ESBL-producing bacteria. Sulbactam-durlobactam retains activity against a number of β-lactamases produced by *Acinetobacter-baumannii-calcoaceticus* complex, including ESBL and carbapenemases.

Amoxicillin-clavulanic acid is recommended for the outpatient treatment of comorbid patients with community-acquired pneumonia, acute otitis media, and prophylaxis of infections resulting from animal and human bites. The Infectious Diseases Society of America (IDSA) considers amoxicillin-clavulanic acid to be the antibacterial of choice in the treatment of acute bacterial rhinosinusitis. The roles of the parenteral penicillin–β-lactamase inhibitors include the treatment of polymicrobial infections such as peritonitis from a ruptured bowel, osteomyelitis in a patient with diabetes, or traumatic osteomyelitis.

When piperacillin-tazobactam is used to treat *Pseudomonas* infections, increased dosages (200–300 mg/kg/day of the piperacillin component) should be used. Non-pseudomonal infections can be treated with lower doses (100–200 mg/kg/day of the piperacillin component). Taking advantage of pharmacokinetics and pharmacodynamics, extended infusions of piperacillin-tazobactam may be superior to intermittent bolus dosing in the treatment of serious bacterial infections and febrile neutropenia.

Sulbactam-durlobactam is approved for the treatment of hospital-acquired bacterial pneumonia and ventilator-associated bacterial pneumonia where the causative pathogen is *Acinetobacter-baumannii-calcoaceticus* complex. Two grams (1 g sulbactam, 1 g durlobactam) are administered every 6 hours using a prolonged 3-hour intravenous infusion.

4. Antistaphylococcal Penicillins

Oxacillin, cloxacillin, dicloxacillin, and **nafcillin** are resistant to degradation by β-lactamases produced by staphylococci. They are superior to vancomycin in the treatment of serious infection due to methicillin-susceptible *S aureus*. They are less active in vitro than natural penicillins against nonstaphylococcal gram-positive bacteria; however, they are still effective in the treatment of certain streptococcal infections, including skin and soft tissue infections due to group A streptococci.

The primary route of clearance of the above agents is nonrenal—thus, no dosage adjustment is needed with decreased kidney function.

TOXICITY & ADVERSE EVENTS

All penicillins can be associated with allergic reactions, ranging from serious IgE-mediated reactions, including anaphylaxis and bronchospasm, to non–IgE-mediated reactions, such as maculopapular rash. The incidence of anaphylaxis to penicillins is estimated to be 0.004–015%, with a fatality rate of 0.0015–0.002%. Only a minority of patients who claim allergy to penicillin will have a true anaphylactic reaction with subsequent exposure to penicillins. *It is important to distinguish "true" allergies to penicillin versus reactions that are not life-threatening or represent antibiotic intolerance* given that avoidance of β-lactams in patients with reported allergy results in increased adverse events, increased risk for *Clostridioides difficile* superinfection, and decreased clinical efficacy.

Of the oral penicillins, amoxicillin-clavulanate is more commonly associated with diarrhea due to the clavulanate component. Nafcillin administered at high doses is associated with modest leukopenia, and oxacillin has been linked with a higher incidence of liver toxicity than other agents in this class. The combination of piperacillin-tazobactam and vancomycin has been associated with increased risk of nephrotoxicity when compared with other vancomycin–β-lactam combinations in observational studies. However, increased nephrotoxicity was not found with receipt of piperacillin-tazobactam compared to cefepime in a recent RCT.

Cephalosporins

Katherine Gruenberg
Emily Kaip

The cephalosporins, structurally related to the penicillins, consist of a β-lactam ring attached to a dihydrothiazine ring. Substitutions of chemical groups result in varying pharmacologic properties and antimicrobial activities. Type 1 allergic cross-reactions between penicillins and cephalosporins are primarily due to similarities in the molecular structure of the R1 side chains instead of the core β-lactam structure or the R2 side chains; for example, penicillin and cefoxitin, as well as ampicillin (or amoxicillin) and cephalexin, share similar R1 side chains. Consequently, a patient with a type 1 reaction to penicillin may experience a similar reaction with cefoxitin, and a patient with an allergic reaction to ampicillin would be more likely to have a reaction to cephalexin than cefoxitin.

The mechanism of action of cephalosporins is analogous to that of the penicillins: (1) binding to specific penicillin-binding proteins, (2) inhibition of cell wall synthesis, and (3) activation of autolytic enzymes in the cell wall. Resistance to cephalosporins may be due to poor permeability of the medication into bacteria, lack of penicillin-binding proteins, or degradation by β-lactamases.

Cephalosporins have been divided into five major groups or "generations" based on their antibacterial activity: First-generation cephalosporins have good activity against aerobic gram-positive organisms (but not *Enterococcus*) and some community-acquired gram-negative organisms (*P mirabilis, Escherichia coli*, *Klebsiella* species); second-generation cephalosporins have a slightly extended spectrum against aerobic gram-negative bacteria, and some are active against certain gram-negative anaerobes (eg, cefoxitin); and third-generation cephalosporins are active against many aerobic gram-negative bacteria. Not all cephalosporins fit neatly into this grouping, and there are exceptions to the general characterization of the medications in the individual classes. Cefepime is considered a fourth-generation agent because it is more stable against plasmid-mediated β-lactamase with little or no β-lactamase–inducing capacity. Cefepime compares favorably with ceftazidime with respect to its gram-negative activity; however, its stability versus plasmid-mediated β-lactamase results in improved coverage over ceftazidime against *Enterobacter* and *Citrobacter* species.

The gram-positive coverage of cefepime approaches that of cefotaxime or ceftriaxone. *None of the available cephalosporins are active against Enterococcus.* A fifth-generation cephalosporin, ceftaroline, is active against methicillin-resistant *S aureus* (MRSA) and has comparable gram-negative spectrum activity to ceftriaxone. Ceftobiprole, another fifth-generation cephalosporin with MRSA activity, is available in many countries and was recently approved in the United States. Two cephalosporin–β-lactamase inhibitor combinations are available, ceftazidime-avibactam and ceftolozane-tazobactam, which increase activity against multidrug-resistant *Pseudomonas* and ESBL-producing *E coli* and *Klebsiella* spp. Ceftazidime-avibactam also generally retains activity against carbapenemase producing Enterobacterales. Cefiderocol is a novel siderophore cephalosporin with activity against a variety of multidrug-resistant gram-negative organisms, such as *Acinetobacter baumannii* complex, *E coli*, *E cloacae* complex, *Klebsiella pneumoniae,* and *P aeruginosa*.

1. First-Generation Cephalosporins

Antimicrobial Activity

In vitro activity includes coverage of gram-positive cocci, including viridans streptococci, group A streptococci, and methicillin-susceptible *S aureus.* First-generation cephalosporins are inactive against enterococci (similar to all cephalosporins) and methicillin-resistant staphylococci. Activity against *H influenzae* is poor, and both intermediately and highly penicillin-resistant streptococci are resistant to first-generation cephalosporins. Among gram-negative bacteria, *E coli, K pneumoniae*, and *P mirabilis* are the most likely to be susceptible. Anaerobic gram-positive cocci are usually susceptible, but *B fragilis* is not.

Pharmacokinetics & Administration

A. Oral

Cephalexin and **cefadroxil** are generally well absorbed. Cefadroxil, because of its longer half-life, can be given twice daily instead of four times daily.

B. Intravenous

Cefazolin is preferred because its longer half-life allows for less frequent dosing. In kidney disease, cefazolin requires dosage adjustment.

C. Intramuscular

Cefazolin can be given intramuscularly; however, because it must be administered every 8 hours, the intravenous route is preferred.

Clinical Uses

Oral medications are used for treatment of UTIs and minor skin and soft tissue infections (eg, cellulitis, soft tissue abscess). However, the increase in the incidence of *community-associated MRSA (CA-MRSA)* has limited the use of these agents in some instances.

Intravenous first-generation cephalosporins are the antibacterial agents of choice for prophylaxis of infection of most clean surgical procedures; however, those institutions with high rates of postoperative surgical site infection due to methicillin-resistant staphylococci may consider the use of alternative agents, such as vancomycin. The second-generation cephalosporins cefoxitin and cefotetan have expanded anaerobic activity and are superior to first-generation agents for prophylaxis of infection following elective colorectal surgery or hysterectomy, where anaerobic infections are more likely.

First-generation cephalosporins have historically not been used in the treatment of meningitis because they are less potent than third-generation agents and have insufficient data supporting penetration into CSF; however, emerging, retrospective data suggest that cefazolin, in higher doses, may be a suitable alternative for CNS infections due to methicillin-susceptible *S aureus* (MSSA) in patients who cannot tolerate anti-staphylococcal penicillins due to adverse effects.

2. Second-Generation Cephalosporins

Second-generation cephalosporins are a heterogeneous group with marked individual differences in activity and pharmacokinetics. In general, second-generation cephalosporins show similar activity against gram-negative organisms as first-generation cephalosporins with additional aerobic gram-negative activity. Indole-positive *Proteus* and *Klebsiella* (including first-generation cephalosporin-resistant strains) as well as *M catarrhalis* are usually sensitive to parenteral second-generation agents. Cefuroxime is active against *H influenzae*, including β-lactamase–producing strains, but has little activity against *B fragilis*. In contrast, cefoxitin and cefotetan are active against select anaerobes, including many strains of *B fragilis*. Against gram-positive organisms, second-generation agents are generally less active than the first-generation cephalosporins (cefuroxime is an exception). Second-generation agents have no activity against *P aeruginosa*.

Pharmacokinetics & Administration

A. Oral

Only **cefaclor, cefuroxime axetil**, and **cefprozil** can be given orally. They are less active than amoxicillin against *Streptococcus pneumoniae*. Cefuroxime axetil is de-esterified to cefuroxime after absorption. Its longer half-life permits twice-daily dosing, and absorption is enhanced when it is taken with food.

B. Intravenous and Intramuscular

Because of differences in medication half-life and protein binding, peak serum levels achieved and dosing intervals vary greatly for these medications. Medications with shorter half-lives (eg, **cefoxitin**) require more frequent dosing than medications with longer half-lives (eg, **cefuroxime**). Dosage adjustment is required with kidney disease.

Clinical Uses

Similar to amoxicillin-clavulanate, cefprozil and cefuroxime axetil are recommended in the treatment of sinusitis and otitis media in patients unresponsive to amoxicillin due to their activity against β-lactamase–producing *H influenzae* and *M catarrhalis*.

Considering their activity against *B fragilis*, cefoxitin and cefotetan can be used to treat mixed anaerobic infections, eg, peritonitis and diverticulitis, as well as prophylaxis for colorectal surgery, vaginal or abdominal hysterectomy, and appendectomy. However, since many *B fragilis* and enteric gram-negative organisms are increasingly resistant to cefoxitin and cefotetan, alternative agents are preferred for serious intra-abdominal infections and as prophylaxis for some surgical procedures.

3. Third-, Fourth-, & Fifth-Generation Cephalosporins

Antimicrobial Activity

Most of these medications are active against staphylococci but less so than first-generation cephalosporins. **Ceftazidime**, however, has notably weak activity against *S aureus* and pneumococci. While inactive against enterococci, most third- and fourth-generation cephalosporins inhibit most streptococci (ceftazidime is an exception to this rule). **Ceftriaxone, cefotaxime**, and **ceftaroline** offer the most reliable antipneumococcal coverage. *A major advantage of third-, fourth-, and fifth-generation cephalosporins over the first and second generations is their expanded gram-negative coverage.* In addition to organisms inhibited by other cephalosporins, they are more active against *Serratia marcescens*, *Providencia*, *Haemophilus*, and *Neisseria*, including β-lactamase–producing strains. Ceftazidime is unique among all third-generation agents because it is active against *P aeruginosa.* Pseudomonal species other than *P aeruginosa* are often resistant to third-generation cephalosporins, and *Listeria* is uniformly resistant. Activity against *B fragilis* is variable. In contrast to the third-generation agents, **cefepime**—the only fourth-generation cephalosporin available in the United States—is more active against *Enterobacter* and *Citrobacter*, has activity comparable to that of ceftazidime against *P aeruginosa*, and has gram-positive activity similar to ceftriaxone. Cefepime has demonstrated equal efficacy to carbapenems for the treatment of *Enterobacter* and can potentially spare the use of broader-spectrum agents. Among the cephalosporins, cefepime is used frequently in the treatment of multidrug-resistant *P aeruginosa*, specifically by an extended infusion to maximize the time-dependent pharmacodynamics. While cefepime is sometimes active in vitro against ESBL-producing organisms, it is clinically less reliable compared with carbapenems. Administering cefepime as an extended infusion can also be considered as an option for isolates with elevated cefepime minimum inhibitory concentrations. **Cefiderocol** is a siderophore cephalosporin sharing structural similarities with both cefepime and ceftazidime, but with a novel mechanism of action. Cefiderocol uses the bacterial iron transport system to enter the bacterial cell, allowing it to bypass resistance mechanisms, such as porin alterations. Cefiderocol is the only available cephalosporin without a coformulated β-lactamase inhibitor that retains activity against multidrug-resistant gram-negative organisms, including *Pseudomonas, Acinetobacter baumannii, Stenotrophomonas maltophilia*, and carbapenem-resistant *Enterobacterales* (CRE).

Cefpodoxime proxetil, cefdinir, cefditoren pivoxil, cefixime, and **ceftibuten** (the only oral agents in this group) are more active than cefuroxime axetil against gram-negative pathogens. However, none of these oral agents are as active as the parenteral third-generation cephalosporins against these bacteria. All third- and fourth-generation cephalosporins are uniformly active against *S pyogenes* (group A *Streptococcus*). Cefpodoxime proxetil, cefditoren pivoxil, and cefdinir are active against methicillin-susceptible *S aureus*, whereas ceftibuten has limited activity; none are active against methicillin-resistant strains. Cefdinir, cefditoren pivoxil, and cefpodoxime proxetil are active against penicillin-susceptible strains of *S pneumoniae* (the pneumococcus), but ceftibuten has marginal activity. None of the oral cephalosporins are reliable against intermediately susceptible or penicillin-resistant *S pneumoniae*. Similar to other members of this class, these medications are ineffective against enterococci and *Listeria monocytogenes*.

Prior to FDA approval of ceftobiprole, **ceftaroline** was the only β-lactam available in the United States with in vitro activity against MRSA. Unlike other β-lactams, ceftaroline binds PBP2a, a penicillin-binding protein encoded by the mecA gene in MRSA. The gram-negative spectrum of activity of ceftaroline approximates that of ceftriaxone; thus, it is inactive against *P aeruginosa, Acinetobacter* species (spp), and *B fragilis*. Ceftobiprole, which has been approved for use in the United States, has a similar spectrum of activity to that of ceftaroline including MRSA and some gram-negatives, with the added benefit of *Pseudomonas* coverage. Both ceftaroline and ceftobiprole may be used for the treatment of pneumonia, acute bacterial skin infections, and complicated MRSA bacteremia.

Pharmacokinetics & Administration

The intravenous third- and fourth-generation agents distribute into extracellular fluid and reach levels in the CSF exceeding those needed to inhibit susceptible pathogens, particularly in the presence of inflamed meninges. The CSF penetration of ceftaroline is minimal; however, successful use of ceftaroline in the treatment of complicated MRSA CNS infections, such as meningitis, has been reported. Case reports suggest that cefiderocol reaches therapeutic drug concentrations in the CSF. Cefiderocol is approved for the treatment of complicated UTIs and hospital-acquired or ventilator-associated bacterial pneumonia at a dose of 2 g every 8 hours as a 3-hour extended intravenous infusion. Primarily excreted in the urine, cefiderocol must be dose-reduced in patients with impaired kidney function; a higher dose of 2 g every 6 hours is recommended in patients with creatinine clearance > 120 mL/min. Ceftobiprole is dosed at 667 mg every 8 hours, with dose reductions, frequency reductions, or both recommended for patients with impaired creatinine clearance. Higher doses (ie, 667 mg every 6 hours) may be considered for bloodstream infections.

The half-lives of the third-, fourth-, and fifth-generation agents vary, resulting in differing dosage frequency. Ceftriaxone has the longest half-life and differs from the others in that it is eliminated primarily by biliary excretion; no dosage adjustment is required in kidney disease.

Clinical Uses

Because of their penetration into the CSF and potent in vitro activity, intravenous third-generation cephalosporins are effective in the treatment of meningitis due to susceptible pneumococci, meningococci, H influenzae, and certain enteric gram-negative bacilli. In older patients with meningitis, empiric therapy should include a third-generation cephalosporin combined with ampicillin or trimethoprim-sulfamethoxazole to cover *L monocytogenes*. Ceftazidime has been used to treat meningitis due to *Pseudomonas*. The dosage for meningitis should be at the upper limits of the recommended range, because CSF levels of these medications are only 10–20% of serum levels. Cefepime is frequently administered empirically for febrile neutropenia due to its activity against *Pseudomonas*, most enteric *Enterobacterales*, and streptococci. Ceftriaxone is indicated for gonorrhea, chancroid, and more serious forms of Lyme disease. Because of its long half-life and once-daily dosing requirement, ceftriaxone is widely used in the outpatient parenteral therapy of infections due to susceptible organisms.

Cefepime is useful for isolates resistant to third-generation cephalosporins, such as *Enterobacter* and *Citrobacter*. Ceftaroline is useful in the treatment of skin and soft tissue infections due to MRSA, particularly with coinfecting gram-negative pathogens. Cefiderocol is generally reserved for multidrug-resistant infections with few to no other antimicrobial options.

Cefdinir, cefditoren pivoxil, and cefpodoxime proxetil are the most active oral third-generation agents against pneumococci and *S aureus*. Cefixime is available in an oral suspension and tablets and has been used as an alternative treatment for uncomplicated gonorrhea (rather than ceftriaxone).

4. Cephalosporins Combined With β-Lactamase Inhibitors

Similar to the penicillin–β-lactamase inhibitor combinations, two cephalosporin–β-lactamase inhibitor combinations are available, **ceftazidime-avibactam** and **ceftolozane-tazobactam.** The addition of avibactam to ceftazidime results in activity against ceftazidime-resistant

Enterobacterales and *Pseudomonas*, including ESBL, AmpC, and KPC enzymes. Similarly, the combination of ceftolozane and tazobactam increases coverage of some AmpC β-lactamases and multidrug-resistant *P aeruginosa*. Both agents distribute comparably to other cephalosporins and are eliminated by the kidneys. The dose of ceftazidime-avibactam is 2 g of ceftazidime (with 500 mg avibactam) as a 2-hour infusion every 8 hours, though some experts recommend a 3-hour infusion for infections caused by carbapenem-resistant *Enterobacterales*, resistant *Pseudomonas*, and *Stenotrophomonas.* Ceftazidime-avibactam is approved for the treatment of complicated UTIs, including pyelonephritis, intra-abdominal infections (in combination with metronidazole), and hospital-acquired and ventilator-associated bacterial pneumonia. The dose of ceftolozane-tazobactam is 1 g of ceftolozane (with 500 mg tazobactam) every 8 hours given as a 1-hour infusion for intra-abdominal infections (in combination with metronidazole) and for UTIs, including pyelonephritis. An increased dose of 2 g of ceftolozane (with 1 g tazobactam) every 8 hours given as a 3-hour infusion is recommended for the treatment of hospital-acquired or ventilator-associated bacterial pneumonia, or for serious, resistant gram-negative infections. Importantly, neither agent is active against anaerobes, including *B fragilis;* thus, the addition of metronidazole is needed for the treatment of intra-abdominal infections. The scope of adverse events and drug interactions is comparable to the other later generation cephalosporins.

5. Adverse Effects of Cephalosporins

Allergy

Cephalosporins, like penicillins, can be associated with a variety of hypersensitivity reactions, including anaphylaxis, fever, skin rashes, nephritis, and hemolytic anemia. *The frequency of IgE cross-allergy between cephalosporins and penicillins approximates 2–17%. However, the risk of cross-reactivity is dependent on the specific cephalosporin*. Cross-reactivity between penicillin and cephalosporins is more common with first-generation agents, when compared with later generations. The exception is cefazolin, which has low cross-reactivity with penicillin due to its distinct side chain. Cephalosporin allergy in penicillin-allergic patients is attributable to cross-reactive antibodies to R1 side chains with similarity to penicillin or amoxicillin. *Persons with a history of anaphylaxis to penicillins should undergo allergy testing (eg, penicillin skin test) before receiving cephalosporins with similar side chains.* The likelihood of non–IgE-mediated cross-reactivity between penicillins and cephalosporins is unknown but likely very low. Allergies to a given agent may or may not extend to the entire cephalosporin class.

Toxicity

Ceftriaxone has been associated with a dose-dependent biliary sludging syndrome and cholelithiasis due to precipitation of medication when its solubility in bile is exceeded. Long-term administration of 2 g/day or more is a risk factor for this complication. Cefepime and ceftazidime have been associated with an increased rate of neurotoxicity, particularly with large doses and concomitant kidney disease.

Other β-Lactam Medications

Katherine Gruenberg
Emily Kaip

MONOBACTAMS

Aztreonam is the sole marketed monobactam, so named due to its monocyclic β-lactam ring resistant to many β-lactamases. Aztreonam is active against gram-negative organisms (including *Pseudomonas*) but has *no activity against gram-positive organisms or anaerobes*. Aztreonam resembles ceftazidime with its gram-negative activity. Thus, it is generally strong against *E coli, Klebsiella, Proteus*, and *Pseudomonas* spp, but its activity is unpredictable against *Acinetobacter, Enterobacter*, and *Citrobacter* spp. Clinical uses of aztreonam are limited because of the availability of third-generation cephalosporins with a broader spectrum of activity and minimal toxicity. However, the clinical role of aztreonam will likely expand as it has been approved in some countries in combination with the β-lactamase inhibitor avibactam for the management of metallo-β-lactamase–producing Enterobacterales (eg, *E coli, Klebsiella, Proteus*), for which few other therapies are available. Considering its activity against *P aeruginosa*, aztreonam is also useful in the management of patients with cystic fibrosis as an inhaled dose of 75 mg administered three times daily. Despite the structural similarity of aztreonam to penicillin, IgE cross-reactivity does *not* exist, and it can therefore be used in patients with IgE-mediated penicillin allergy.

CARBAPENEMS & CARBAPENEMS IN COMBINATION WITH β-LACTAMASE INHIBITORS

This class of medications is structurally related to β-lactam antibiotics with a broad spectrum of activity that includes most gram-negative rods (including *P aeruginosa*), gram-positive organisms, and anaerobes. Carbapenems are inactive against *Burkholderia cepacia, S maltophilia, E faecium*, MRSA, and methicillin-resistant *Staphylococcus epidermidis.* There are four carbapenem antibiotics: **imipenem, meropenem, doripenem**, and **ertapenem.**

Meropenem, doripenem, and imipenem have a similar spectrum of activity and pharmacology. Of particular importance, *the carbapenems are the most reliable agents in the treatment of infection secondary to ESBL-producing E coli and Klebsiella spp*. The emergence of CRE throughout the world is of particular concern because limited options are available to treat these infections, which are associated with high morbidity and mortality. All four carbapenems have been associated with neurotoxicity, particularly seizures. Meropenem and doripenem are less likely to be associated with seizures when compared with imipenem, although the risk of seizures is low with imipenem if dosage is appropriately adjusted for kidney dysfunction. Meropenem and doripenem are associated with less nausea and vomiting than imipenem, a feature of importance when high doses must be used, as in the treatment of *Pseudomonas* infection in patients with cystic fibrosis. The usual dose for meropenem is 1–2 g intravenously every 8 hours. Dosage adjustment is required in kidney dysfunction. Doripenem (500 mg–1 g intravenously every 8 hours) has been used in the treatment of intra-abdominal infection and pyelonephritis, but is no longer available in some countries. In the treatment of ventilator-associated pneumonia, doripenem (administered for 7 days) was associated with increased mortality when compared with imipenem (administered for 10 days). Imipenem is coformulated with cilastatin, an enzyme that enhances the pharmacokinetics and minimizes the nephrotoxic effects of imipenem. The dose and dosing interval of imipenem/cilastatin vary depending on the pathogen susceptibility profile and kidney function.

Ertapenem is similar to the other carbapenems in its activity against aerobic gram-positive and anaerobic organisms, but it is inactive against *Pseudomonas* and *Acinetobacter.* Because of its long half-life (4 hours), it can be administered once daily. The usual dose is 1 g intravenously every 24 hours, and adjustments are needed for kidney dysfunction.

In patients hospitalized for a prolonged period with high severity of illness or with presumed infection caused by a multidrug-resistant organism, empiric use of carbapenems is reasonable. However, ertapenem should not be used if *Pseudomonas* and *Acinetobacter* are suspected. *Pseudomonas* may rapidly develop resistance to carbapenems; however, combination anti-pseudomonal therapy does not decrease the rate of resistance. The use of imipenem or meropenem alone is as effective as combination therapy in patients with febrile neutropenia and certain polymicrobial infections such as peritonitis and pelvic infections.

The most common adverse effects of carbapenems are diarrhea, reactions at the infusion site, and skin rashes. Seizures, nausea, and vomiting are more commonly observed with imipenem. Patients allergic to penicillins may not necessarily be allergic to imipenem and meropenem as well, as *the rate of cross-reactivity is < 1%*.

Meropenem is also available coformulated with vaborbactam, a novel β-lactamase inhibitor. Meropenem-vaborbactam has demonstrated superiority to the best available therapies (polymyxins, carbapenems, aminoglycosides, tigecycline, or ceftazidime-avibactam) in the treatment of CRE infections. Imipenem-cilastatin in combination with relebactam, a β-lactamase inhibitor, is approved for the treatment of complicated urinary tract, intra-abdominal infections, and hospital-acquired or ventilator-associated bacterial pneumonia. Relebactam is structurally similar to avibactam with similar activity against β-lactamases such as ESBLs and KPC-producing Enterobacterales. These carbapenem-β-lactamase inhibitors offer valuable options over more toxic agents, such as colistin and polymixin. The adverse event profile of these combination products mimics that of the parent carbapenem antibiotics.

e1-04

Erythromycin Group (Macrolides)

Katherine Gruenberg
Emily Kaip

The macrolides are a group of closely related compounds characterized by a macrocyclic lactone ring with various sugars attached. Representative antibiotics include the azide compounds (**erythromycin, azithromycin, clarithromycin**), and **fidaxomicin.**

ANTIMICROBIAL ACTIVITY

Erythromycins inhibit protein synthesis by binding to the 50S subunit of bacterial ribosomes. While they are generally bacteriostatic, they can be bactericidal for certain organisms. Similar to penicillin, the rate of macrolide-resistant *S pneumoniae* is high (25–35%), and increased erythromycin resistance in group A streptococci is a concerning threat, according to the CDC. Erythromycin-resistant pneumococci are resistant to azithromycin and clarithromycin as well. *Chlamydia pneumoniae, Mycoplasma, Legionella*, and *Campylobacter* organisms are susceptible to all the macrolides. In contrast to *C pneumoniae*, infection due to *C trachomatis* has been associated with clinical failure (more commonly than with doxycycline) and this failure has sometimes been associated with in vitro macrolide resistance.

PHARMACOKINETICS & ADMINISTRATION

Preparations for oral use include erythromycin base, erythromycin stearate, estolate, and ethyl succinate. Erythromycins are excreted primarily nonrenally therefore, *no adjustment is required in kidney dysfunction*. Azithromycin is available for oral and intravenous use. Clarithromycin is only available as enteral preparations in the United States, but an intravenous preparation is available outside of the United States.

CLINICAL USES

Macrolides are effective in the treatment of infection due to *Legionella, Mycoplasma, Ureaplasma, Corynebacterium* (including diphtheria), *Chlamydia*, and *Chlamydophila* (including ocular and respiratory infections) organisms. As stated earlier, azithromycin (and other macrolides) are inferior to doxycycline in the treatment of *Chlamydia* STIs. They are useful alternatives in the treatment of certain patients with a serious penicillin allergy. When administered early, erythromycin may shorten the course of *Campylobacter* enteritis. Erythromycins are effective against certain *Bartonella* species (bacillary angiomatosis) and *Rhodococcus* species. Clarithromycin, in combination with PPIs, is useful in the treatment of *Helicobacter pylori*, however, resistance is commonly reported. Treatment of atypical mycobacteria infections, particularly *Mycobacterium avium* complex, frequently include azithromycin or clarithromycin in combination with other active therapeutics.

These agents are also sometimes used for their anti-inflammatory action. In vitro data suggest that macrolides have a direct effect on neutrophil function and the production of cytokines associated with inflammation. *Nonantibacterial benefits associated with the macrolides (azithromycin) include the prevention of cystic fibrosis, bronchiectasis, or COPD exacerbations in select patients.*

ADVERSE EFFECTS

Nausea, vomiting, and diarrhea may occur after oral or intravenous administration. Erythromycins—particularly the estolate—can produce acute cholestatic hepatitis (fever, jaundice, impaired liver function), probably as a hypersensitivity reaction. Reversible auditory impairment occurs with high prolonged dosing, particularly in patients with impaired kidney or liver function. Clarithromycin and erythromycin have been associated with prolongation of the QT interval and torsades de pointes, more commonly in women. Erythromycins (and clarithromycin) can increase the effects of certain oral anticoagulants, colchicine, digoxin, theophylline, selected calcium channel blockers, and cyclosporine by inhibiting cytochrome P450. An increased risk of cardiac-associated death has been reported with clarithromycin and erythromycin in some studies, particularly in patients receiving concomitant inhibitors of cytochrome P450 3A4, but a systematic review and network meta-analysis did not identify a significant association between macrolides and cardiovascular mortality.

1. Azalides

Antimicrobial Activity

Azalides (azithromycin, clarithromycin, and others) are structurally closely related. They are similar to erythromycin in activity against most organisms with slightly more activity in vitro against *H influenzae* (azithromycin > clarithromycin > erythromycin) than erythromycin. They are also active against *C trachomatis, Ureaplasma urealyticum*, and *Haemophilus ducreyi*. In addition, these medications have in vitro activity against several unusual pathogens, including atypical mycobacteria (*Mycobacterium avium-intracellulare, Mycobacterium chelonei, Mycobacterium fortuitum, Mycobacterium marinum*), *Toxoplasma gondii, Campylobacter jejuni, H pylori*, and *Borrelia burgdorferi*.

Pharmacokinetics & Administration

Azithromycin and clarithromycin are more acid-stable than erythromycin, concentrating intracellularly and within tissues. Azithromycin has a long terminal half-life, with high tissue concentrations that persist for days. While elevated tissue levels associated with azithromycin and clarithromycin has been proposed to overcome the high incidence of in vitro resistance seen with pneumococci (30%), in vitro resistance has been associated with clinical failure.

Clinical Uses

Azithromycin and clarithromycin are approved for the treatment of streptococcal pharyngitis, uncomplicated skin infections, community-acquired pneumonia, and acute bacterial exacerbations of chronic bronchitis. When prescribing these agents in the treatment of pharyngitis in young adults, caution should be used due to the increased risk for *Fusobacterium necrophorum*, the etiologic agent in Lemierre syndrome. Morbidity and mortality in this patient population have been estimated to be substantially greater than that associated with infectious complications associated with *S pyogenes*. While penicillins and cephalosporins are active against *Fusobacterium necrophorum*, macrolides are predictably inactive.

Because of the long half-life, outpatient oral treatment with azithromycin can be administered once daily for a total of 5 days (500 mg on day 1 and then 250 mg on days 2–5). Clarithromycin is usually administered in a dosage of 250–500 mg orally twice daily, although an extended-release formulation that is given as a single daily 1000-mg dose is approved for acute sinusitis and acute exacerbation of chronic bronchitis. *The less frequent dosing and improved tolerability of azithromycin, as well as its propensity for fewer drug interactions, makes it a preferable choice over erythromycin or clarithromycin in most patients.*

Azithromycin as a single dose (1 g) is an alternative therapy for chlamydial genital infections; *it is no longer recommended first-line due to lower cure rates for rectal chlamydia infection compared with doxycycline*. Azithromycin is used as single-dose therapy (1 g) for chancroid. For nongonococcal urethritis, azithromycin should only be used as an alternative to doxycycline due to increased resistance among *M genitalium* and lower cure rates. A single dose of azithromycin (20 mg/kg, maximum dose of 1 g) is effective in treating trachoma and substantially reduces disease burden in endemic areas. While effective in the treatment of trachoma, mass distribution has been associated with increased circulation of macrolide-resistant *S pneumoniae*. A 1-g dose of azithromycin is also effective therapy for severe cholera. The spectrum of activity of the macrolides—particularly their atypical coverage—results in their recommendation as monotherapy in select mild cases of community-acquired pneumonia or in combination with β-lactams for comorbid patients with community-acquired pneumonia. *The IDSA recommends azithromycin monotherapy only in areas with pneumococcal resistance rates < 25%*. Azithromycin taken daily for 1 year has been found to decrease the frequency of exacerbations of COPD and improved quality of life; however, cochlear toxicity and isolation of azithromycin-resistant bacterial isolates have been observed with long-term therapy. Similarly, early administration of azithromycin in young children with recurrent severe lower respiratory tract infections has been associated with a decreased likelihood of severe lower respiratory tract infection. Azithromycin is not useful for acute exacerbations of asthma. Azithromycin is effective in the treatment of dysentery caused by multidrug-resistant *Shigella* and *Campylobacter* organisms.

Clarithromycin has been used for the therapy of *M avium* complex infections, usually in combination with other medications (eg, rifabutin and ethambutol), and can be given twice daily (500 mg twice daily) or three times weekly (1000 mg) as intermittent therapy. Oral clarithromycin (500 mg twice daily for 6 months), in combination with other agents, is effective therapy for disseminated *M chelonei* infections. Clarithromycin has been used as part of combination regimens for *H pylori*, but rising resistance rates have prompted newer guidance to recommend against its use unless susceptibility is confirmed.

Adverse Effects

Adverse effects of azithromycin and clarithromycin are similar to those of erythromycin, but upper GI upset, the major side effect, occurs less often with the azalides. Hepatic enzyme elevations and reversible cochlear toxicity have been reported. Clarithromycin is similar to erythromycin in its inhibition of the cytochrome P450 system. Drug interactions between clarithromycin and calcium channel blockers as well as between clarithromycin and statins are associated with increased 30-day risk of hospitalization with AKI. Azithromycin is associated with minimal drug interactions. Macrolides prolong QT in patients at risk (eg, patients receiving concomitant agents known to prolong QT, history of prolonged QT). The FDA has warned against using clarithromycin in patients with heart disease based on increased cardiac-related adverse events or mortality.

2. Fidaxomicin

Fidaxomicin is a *nonabsorbed* macrolide approved for the treatment of *C difficile* infection. Compared with vancomycin, fidaxomicin, 200 mg twice daily for 10 days, demonstrates similar cure rates in the treatment of this infection. However, fidaxomicin has been associated with fewer recurrences of *C difficile* infection compared with oral vancomycin. *For patients with an initial C difficile infection episode, guidelines recommend fidaxomicin rather than a standard course of vancomycin.* However, this recommendation also acknowledges that fidaxomicin's considerable acquisition cost is a barrier to its use in most patients with this disease. The most common adverse events reported in clinical trials include nausea and vomiting.

Tetracycline Group

Katherine Gruenberg
Emily Kaip

e1-05

The tetracyclines are a group of medications with common basic chemical structures, antimicrobial activity, and pharmacologic properties.

ANTIMICROBIAL ACTIVITY

Tetracyclines are inhibitors of protein synthesis and are bacteriostatic for many gram-positive and gram-negative bacteria. They reliably inhibit mycoplasmas, rickettsiae, chlamydiae, spirochetes, and some protozoa (eg, amoebas, malaria). Their antipneumococcal activity is superior to the macrolides, and almost all *H influenzae* are inhibited. Tetracyclines, particularly derivatives tigecycline, omadacycline, and eravacycline, also have some activity against some *vancomycin-resistant enterococci (VRE).* **Doxycycline** and **minocycline** are potential options for treatment of *S aureus* infections, including some methicillin-resistant strains. Tetracycline-resistant staphylococci often retain susceptibility to doxycycline and minocycline, and doxycycline-resistant *S aureus* can still be susceptible to minocycline. Tetracyclines other than tigecycline, omadacycline, and eravacycline have little utility in the treatment of gram-negative aerobic infection. However, minocycline tends to retain activity against *S maltophilia* and multidrug-resistant *Acinetobacter*. For treatment of multidrug-resistant gram-negative infections, the IDSA recommends to dose minocycline at 200 mg orally every 12 hours. Receipt of doxycycline in combination with ceftriaxone in the treatment of community-acquired pneumonia has been associated with a reduction in the rate of associated antibacterial *C difficile* disease. The antibacterial activity of doxycycline against *C difficile* is likely the mechanism of action for this finding.

PHARMACOKINETICS & ADMINISTRATION

Oral bioavailability varies depending on the specific tetracycline. Absorption is impaired by chelation with divalent cations (eg, Ca^{2+} or Fe^{2+}) found in dairy products and medications (eg, aluminum hydroxide gels [antacids]). *All tetracyclines should be staggered at least 2 hours before or after receipt of multivalent cations.* Oral bioavailability is only moderate with tetracycline and best with doxycycline and minocycline (95% or more). Lipid solubility of minocycline and doxycycline accounts for their penetration into the CSF, prostate, tears, and saliva.

Tetracyclines are primarily metabolized in the liver and excreted in bile. Doxycycline and minocycline do not require dosage adjustment in kidney disease; in contrast, tetracycline should be given in reduced dosage.

For patients unable to take oral medication, some tetracyclines (doxycycline, minocycline) are formulated for parenteral administration in doses similar to the oral preparations.

CLINICAL USES

Tetracyclines are medications of choice for most infections due to *Chlamydia, Chlamydophila, Mycoplasma, Rickettsia, Ehrlichia*, and *Vibrio* organisms and for some spirochetal infections. STIs in which chlamydiae often play a role—endocervicitis, urethritis, proctitis, and epididymitis—should be treated with doxycycline for 7–14 days. Doxycycline administered as 200 mg once after unprotected sex may be effective in preventing bacterial STIs in men who have sex with men and take pre-exposure prophylaxis for HIV. Pelvic inflammatory disease is often treated with doxycycline plus cefoxitin or cefotetan. Other chlamydial infections (psittacosis, lymphogranuloma venereum, trachoma) and STIs (granuloma inguinale) also respond to doxycycline. Other uses include treatment of acne, respiratory infections, Lyme disease and relapsing fever, brucellosis, glanders, tularemia (often in combination with streptomycin), cholera, mycoplasma pneumonia, actinomycosis, nocardiosis, malaria, infections caused by *M marinum* and *Pasteurella* species (typically after an animal bite), and as malaria prophylaxis (including multidrug-resistant *P falciparum*). They also have been used in combination with other medications for amebiasis and *H pylori.* With its modest activity against pneumococci (same or better than macrolides) and reliable coverage of *H influenzae, Chlamydophila, Legionella*, and *Mycoplasma* organisms, doxycycline is a potential empiric monotherapy choice in mild cases of community-acquired pneumonia or in combination with β-lactams for patients with community-acquired pneumonia and comorbidities.

Doxycycline and minocycline are options in the treatment of community-onset skin and soft tissue infection due to MRSA. Minocycline is equally as efficacious as doxycycline for the therapy of nongonococcal urethritis and cervicitis.

Adverse Effects

A. Allergy

Hypersensitivity reactions with fever or skin rashes are uncommon.

B. Gastrointestinal Side Effects

Diarrhea, nausea, and anorexia are common. Tetracycline administration, particularly doxycycline and minocycline, should be avoided at bedtime due to the risk of esophageal erosion. In order to prevent this, these agents should be taken with a full glass of water.

C. Bones and Teeth

Tetracyclines are bound to calcium deposited in growing bones and teeth, causing fluorescence, discoloration, enamel dysplasia, deformity, or growth inhibition. Therefore, *tetracyclines should not be given to pregnant individuals, nursing individuals, or children under 8 years of age*. The warning regarding dental staining with tetracyclines and children has existed for decades. However, children treated with doxycycline for suspected Rocky Mountain spotted fever have been found to have no dental staining, enamel hypoplasia, or tooth color differences. Consequently, certain children can likely receive doxycycline in the absence of other options.

D. Liver Damage

Tetracyclines can impair hepatic function or even cause liver necrosis, particularly in the presence of preexisting liver disease.

E. Other

All tetracyclines may induce photosensitization, especially in fair-skinned individuals. Minocycline induces vestibular reactions (dizziness, vertigo, nausea, vomiting), with a frequency of 35–70% associated with doses of 200 mg daily.

Tetracycline Derivatives

Katherine Gruenberg
Emily Kaip

e1-06

Tigecycline, a glycylcycline tetracycline derivative, is available as a parenteral antibacterial for the treatment of nosocomial infection. It is active against most gram-positive bacteria, including methicillin-resistant staphylococci, VRE, and many multidrug-resistant aerobic gram-negative bacilli, including *Acinetobacter*, *Enterobacter*, *Citrobacter*, and ESBL-producing *E coli* and *Klebsiella*. However, tigecycline lacks clinically significant activity against *Pseudomonas* and *Proteus* spp. Tigecycline demonstrates excellent anaerobic activity against *B fragilis* and gram-positive anaerobes. At standard dosing, a loading dose of 100 mg is administered intravenously with maintenance at 50 mg every 12 hours. The IDSA recommends an increased dose (200 mg as a loading dose, then 100 mg every 12 hours) when treating multidrug-resistant gram-negative infections. The medication distributes into deep compartments with a large volume of distribution and low serum levels. Considering the low achievable serum levels associated with tigecycline, this agent should *not* be used in patients with bacteremia or sepsis. The medication is primarily eliminated via biliary/fecal excretion with a half-life of 30–40 hours. Dose adjustment to 25 mg every 12 hours is recommended in Child-Pugh class C liver disease. Tigecycline has a similar adverse effect profile as the tetracyclines; upper GI side effects are particularly common. While approved for complicated skin and soft tissue infection and intra-abdominal infection, the spectrum of activity of tigecycline has resulted in its use in the treatment of certain resistant gram-negative pathogens, including ESBL-producing organisms. Tigecycline has been associated with *increased* mortality in ventilator-associated pneumonia when compared with imipenem. Consequently, its use in sepsis and ventilator-associated pneumonia is not recommended. *Tigecycline has a boxed warning highlighting its increased all-cause mortality.* Tigecycline is also not indicated for treatment of diabetic foot infection or hospital-acquired pneumonia.

Omadacycline is an aminomethylcycline tetracycline derivative, approved for treatment of bacterial community-acquired pneumonia and acute skin and skin structure infections. Available as both a tablet and in an intravenous formulation, omadacycline has activity against *S aureus, S pneumoniae*, viridans group streptococci, *E coli*, *H influenzae*, *M catarrhalis*, atypical bacteria (eg, *Mycoplasma pneumoniae, Legionella pneumophilia*, nontuberculous *Mycobacteria)*, and anaerobes. Omadacycline is also active against the biothreat pathogens *Bacillus anthracis* and *Yersinia pestis*. Similar to tigecycline, omadacycline also retains activity against drug-resistant bacteria, such as MRSA, VRE, and ESBL-producing Enterobacterales. In clinical trials, omadacycline was noninferior to linezolid for the treatment of bacterial skin and skin structure infections and noninferior to moxifloxacin for the treatment of community-acquired pneumonia. *Omadacycline has a warning for higher rates of mortality (2%) compared with moxifloxacin (1%) in the treatment of community-acquired pneumonia*; it is recommended that patients at a high risk (eg, older than 65 years with comorbidities) be monitored while receiving omadacycline for this indication. Omadacycline has shown promise in treating certain nontuberculous mycobacterial (NTM) infections, particularly *M abscessus*. Its oral dosage form makes it a promising option in those who require prolonged therapy, and it may be particularly useful in cases where other options are ineffective due to resistance or intolerance. The adverse effects of omadacycline are similar to other medications in the tetracycline class. Treatment with omadacycline requires a fixed loading dose followed by a fixed, once-daily maintenance dose. If administered orally, patients should fast for at least 4 hours prior to and 2 hours after taking omadacycline and that administration is separated by at least 4 hours from multivalent cations (eg, milk, antacids, multivitamins). One potential benefit of omadacycline over other antibacterials with similar spectrum of activity is that omadacycline does not appreciably induce *C difficile* proliferation.

Eravacycline is a fluorocycline antibiotic with a structure similar to tigecycline. Eravacycline is available as an intravenous solution for the treatment of complicated intra-abdominal infections. Eravacycline has activity against *S aureus, Enterococcus*, Enterobacterales, and anaerobes. Similar to tigecycline and omadacycline, eravacycline also has activity against MRSA, VRE, ESBL-producing Enterobacterales, and carbapenem-resistant *E coli* and *K pneumoniae.* Compared with tigecycline, eravacycline shows more potent in vitro activity against multidrug-resistant gram-negative bacteria. Eravacycline showed noninferiority to meropenem and ertapenem in two phase 3 trials for the treatment of complicated intra-abdominal infections but failed to show efficacy compared with standard therapy for the treatment of complicated UTIs. Similar to tigecycline and omadacycline, the most common side effects that patients experience with eravacycline are nausea and vomiting. Eravacycline is dosed based on weight (1 mg/kg) twice daily.

El Ghali A et al. Long-term evaluation of clinical success and safety of omadacycline in nontuberculous mycobacteria infections: a retrospective, multicenter cohort of real-world health outcomes. Antimicrob Agents Chemother. 2023;67:e0082423. [PMID: 37768312]

Tamma PD et al. Infectious Diseases Society of America 2024 guidance on the treatment of antimicrobial-resistant gram-negative infections. Clin Infect Dis. 2024 Aug. [Epub ahead of print] [PMID: 39108079]

Aminoglycosides

Katherine Gruenberg
Emily Kaip

e1-07

Aminoglycosides are a group of bactericidal medications sharing chemical, antimicrobial, pharmacologic, and toxic characteristics. At present, the group includes **streptomycin, neomycin, kanamycin, amikacin, gentamicin, tobramycin, sisomicin, netilmicin, paromomycin, spectinomycin**, and **plazomicin.** All these agents inhibit protein synthesis in bacteria by inhibiting the function of the 30S subunit of the bacterial ribosome. Resistance is based on (1) a deficiency of the ribosomal receptor (chromosomal mutant); (2) the enzymatic destruction of the medication (plasmid-mediated transmissible resistance of clinical importance) by acetylation, phosphorylation, or adenylylation; or (3) a lack of permeability to the medication molecule or failure of active transport across cell membranes. *Anaerobic bacteria are resistant to aminoglycosides* because transport across the cell membrane is an oxygen-dependent energy-requiring process.

All aminoglycosides are potentially *ototoxic* (cochlear and vestibular) and *nephrotoxic*, although to different degrees. All can accumulate in kidney disease; therefore, dosage adjustments must be made in patients with kidney dysfunction.

Because of their considerable toxicity and the availability of less toxic agents (eg, cephalosporins, quinolones, carbapenems, β-lactamase inhibitor combinations), aminoglycosides are used less often than in the past. They are most commonly used in combination with other agents to treat resistant gram-negative organisms or in low doses with β-lactam medications or vancomycin for their synergistic effect against gram-positive bacterial infection (eg, enterococci, penicillin-resistant viridans streptococci, *S aureus* and *S epidermidis* prosthetic heart valve infections). In 2023, the Clinical & Laboratory Standards Institute (CLSI) decreased the *Enterobacterales* breakpoints for amikacin, gentamicin, and tobramycin, meaning that amikacin, gentamicin, and tobramycin are considered markedly less active against resistant *Enterobacterales*; by contrast, plazomicin is shown to retain good activity. Aminoglycosides are inferior to β-lactams as monotherapy in the treatment of *Pseudomonas* infections, particularly in febrile neutropenic patients. Although aminoglycosides demonstrate in vitro activity against many gram-positive bacteria, they should *never* be used alone to treat infections caused by these organisms—both because there is minimal clinical experience with such infections and because less toxic alternatives are available.

GENERAL PROPERTIES OF AMINOGLYCOSIDES

Because of the similarities of the aminoglycosides, a summary of properties is presented briefly.

A. Absorption, Distribution, Metabolism, and Excretion

Aminoglycosides are not absorbed from the GI tract. They are hydrophilic and distribute well into extracellular fluid, but diffuse poorly into the eye, prostate, bile, CNS, and spinal fluid after parenteral injection. Patients who are volume overloaded (eg, ascites, HF, etc) may need larger doses to meet therapeutic goals, and pharmacokinetics may be less predictable in patients with a fluctuating volume status.

The serum half-life is 2–3 hours in patients with normal kidney function. Excretion is almost entirely by glomerular filtration. Aminoglycosides are removed effectively by hemodialysis or continuous hemofiltration.

B. Dosage and Effect of Impaired Kidney Function

In persons with normal kidney function who have gram-negative infections, the dosage of amikacin and plazomicin is 15 mg/kg/day in a single daily dose; that for gentamicin, tobramycin, or netilmicin is 5–7 mg/kg injected once daily. A single large daily dose of gentamicin, tobramycin, netilmicin, or amikacin is as efficacious as—and no more nephrotoxic than—the originally used dosing every 8–12 hours. Trough aminoglycoside levels should be undetectable in patients with average body composition and kidney function receiving once-daily dosing. Some clinicians recommend serum level sampling 12–18 hours after the dose and extending the interval to every 48–72 hours for patients with elevated serum levels. Others have suggested maintaining the dosage interval but decreasing the dose. Patients with kidney disease, volume overload, or obesity have altered antibiotic clearance or volume of distribution.

Therapeutic drug monitoring of aminoglycoside peak and trough levels is recommended to evaluate both efficacy and safety, particularly in patients with abnormal kidney function or large body composition. When using more frequent dosing (ie, not once daily), troughs > 2 mcg/mL have been associated with an increased incidence of nephrotoxicity. Reduced gentamicin doses (3 mg/kg divided every 8–12 hours) are used synergistically with β-lactams or vancomycin in the treatment of enterococcal endocarditis. However, synergistic gentamicin dosing of 3 mg/kg every 24 hours is preferred for the treatment of endocarditis due to viridans streptococci. The combination of ampicillin with ceftriaxone offers a less toxic option in the treatment of enterococcal endocarditis.

C. Adverse Effects

All aminoglycosides can cause ototoxicity and nephrotoxicity. Compared with their nephrotoxicity, the ototoxicity is more likely to be irreversible and is cumulative, presenting as hearing loss (cochlear damage), noted first with high-frequency tones, or as vestibular damage, manifested by vertigo and ataxia. Amikacin is likely more cochlear-toxic than gentamicin, tobramycin, or netilmicin. Nephrotoxicity is usually reversible and occurs with similar frequency with gentamicin, tobramycin, amikacin, and netilmicin. The risk of nephrotoxicity exists even with synergistic lower doses in the treatment of serious gram-positive bacterial infection. In very high doses, usually associated with irrigation of an inflamed peritoneum, aminoglycosides can be *neurotoxic*, producing a curare-like effect with reversible neuromuscular blockade that results in respiratory paralysis.

1. Streptomycin

The usual dosage of streptomycin is 15–25 mg/kg/day (about 1 g/day) injected in one or two divided doses intramuscularly. If administered over 30–60 minutes, it can also be given intravenously. Streptomycin exhibits all the adverse effects typically associated with the aminoglycosides; however, it has greater vestibular toxicity and probably less nephrotoxicity when compared with gentamicin.

Gram-negative resistance emerges so rapidly and has become so widespread that only a few specific indications for this medication remain: (1) plague and tularemia; (2) endocarditis caused by *Enterococcus* (use in conjunction with penicillin or ampicillin) in strains that are susceptible to high levels of streptomycin (ie, 2000 mcg/mL or less); ceftriaxone, rather than aminoglycosides, is recommended to be added to ampicillin in the treatment of *E faecalis* endocarditis; (3) active tuberculosis when other less toxic medications cannot be used; and (4) acute brucellosis (in combination with tetracycline).

2. Neomycin, Kanamycin, & Paromomycin

These aminoglycosides are closely related, with similar activity and complete cross-resistance. Systemic use has been abandoned because of ototoxicity and nephrotoxicity.

Neomycin, often combined with bacitracin and polymyxin, is a component of several over-the-counter topical ointments and creams. While the medication mixture covers the most likely encountered staphylococci, streptococci, and gram-negative bacteria, *the efficacy of topical application is questionable.* Neomycin or kanamycin can give rise to allergic reactions when applied topically to skin or eye. Oral neomycin is approved for pre-operative bowel preparation prior to colorectal surgery. Although it also has a labeled indication for hepatic encephalopathy, this use has fallen out of favor due to reduced efficacy and risk of adverse effects relative to other treatments available in the United States.

Paromomycin, closely related to neomycin and kanamycin, is poorly absorbed after oral administration and has been used mainly to treat asymptomatic intestinal amebiasis and, in doses of 25–30 mg/kg/day in three divided doses for 7 days, to treat giardiasis in pregnancy. A dosage of 500 mg orally three or four times daily is marginally effective for cryptosporidiosis.

3. Amikacin

Amikacin is a semisynthetic derivative of kanamycin. It is relatively resistant to enzymes that inactivate gentamicin and tobramycin. Many gram-negative enteric bacteria, including many gentamicin-resistant strains of *Proteus, Enterobacter*, and *Serratia* organisms, are inhibited. Similar to gentamicin and tobramycin, 15 mg/kg/day administered every 24 hours is as effective as and no more toxic than every 12-hour dosing. In addition to therapy for serious gram-negative infections, amikacin is sometimes included with other medications for therapy of *M avium* complex and *M fortuitum* complex.

Like all aminoglycosides, amikacin is nephrotoxic and ototoxic (particularly for the auditory portion of the eighth nerve). Medication levels should be monitored as with other aminoglycosides.

4. Gentamicin

Gentamicin doses of 5–7 mg/kg/day produce serum levels sufficient for bactericidal effect against most gram-negative organisms. Enterococci generally are resistant; however, the addition of gentamicin to cell wall active agents, such as penicillin or vancomycin, is associated with increased bactericidal activity against this pathogen. In endocarditis due to viridans streptococci or *E faecalis*, gentamicin in lower synergistic doses (3 mg/kg/day) is combined with penicillin or ampicillin. In kidney disease, the dose should be adjusted as noted above.

5. Tobramycin

Tobramycin closely resembles gentamicin in antibacterial activity, toxicity, and pharmacologic properties and exhibits partial cross-resistance. It is more active than gentamicin against *P aeruginosa* but much less active than gentamicin when used synergistically with penicillin for enterococcal endocarditis. Dosing is the same as for gentamicin. Tobramycin is also given by aerosol (300 mg twice daily) to patients with cystic fibrosis. This improves pulmonary function and decreases colonization with *Pseudomonas* with minimal toxicity and selection for resistant strains.

6. Plazomicin

Plazomicin is a synthetic aminoglycoside antibiotic that retains activity against aminoglycoside-modifying enzymes that render other aminoglycosides ineffective. Plazomicin has good activity against Enterobacterales, including CRE infections, and variable activity against *Pseudomonas* and *Acinetobacter*. Plazomicin is approved for the treatment of complicated UTIs, including pyelonephritis, based on non-inferiority to meropenem for the treatment of these infections in clinical studies. In a small randomized study, plazomicin in combination with meropenem or tigecycline resulted in lower rates of composite mortality or disease complications compared with treatment with colistin and meropenem or tigecycline for patients with CRE bloodstream infections. While this study suggests a possible role for plazomicin in the treatment of CRE, other less toxic alternatives are available.

e1-08

Polymyxins

Katherine Gruenberg
Emily Kaip

The polymyxins (**colistin** and **polymyxin B**) are basic polypeptides that are bactericidal for certain gram-negative aerobic rods, including *Pseudomonas*. Because of poor distribution into tissues and substantial toxicity (primarily nephrotoxicity and neurotoxicity), systemic use of these agents has been limited to infections caused by multidrug-resistant gram-negative organisms that are sensitive only to the polymyxins. Colistin is used for pan-resistant *Acinetobacter baumanii* and *P aeruginosa* and CRE infections. However, safer alternatives are available, such as ceftolozane-tazobactam for multidrug-resistant *P aeruginosa* and ceftazidime-avibactam or meropenem-vaborbactam for CRE infections. The safe, effective use of the polymyxins, including confusion between polymyxin B and colistin, absence of pharmaceutical standards, uncertainties regarding susceptibility testing and breakpoints, pharmacokinetics in special patient populations, and the role of combination therapy limits their utility. As such, the IDSA does not recommend polymyxins for the treatment of CRE infections, although colistin may be used as an alternative treatment for uncomplicated CRE cystitis. Baseline renal impairment and older age strongly predict AKI. Higher doses of colistin are associated with increased microbiologic success and decreased 7-day mortality; however, they are also associated with worsened kidney function. While not proven to improve clinical outcomes, some clinicians recommend capping the dose at 9 million units/daily of colistin methanesulfonate and adding a second medication such as a carbapenem.

e1-09

Lefamulin

Katherine Gruenberg
Emily Kaip

Lefamulin, the only commercially available antibiotic from the pleuromutilin class, is used in community-acquired bacterial pneumonia. Lefamulin has been discontinued in the United States but is still available in other countries.

ANTIMICROBIAL ACTIVITY

Lefamulin halts bacterial protein synthesis by interacting with the 23s ribosomal RNA of the 50S subunit of ribosomes. Lefamulin is active against *S pneumoniae*, *H influenzae*, *M catarrhalis*, atypical bacteria (eg, *M pneumoniae*, *Chlamydophila pneumoniae*, and *Legionella pneumophila*), *S aureus* (including methicillin-resistant strains), *E faecium* (including vancomycin-resistant strains), and *S pyogenes*. It lacks appreciable activity against Enterobacterales and *P aeruginosa*.

PHARMACOKINETICS & ADMINISTRATION

Lefamulin is available as an oral and intravenous formulation dosed twice daily. Oral doses should be separated at least 1 hour before or 2 hours after a meal to maximize absorption. Lefamulin is widely distributed in tissues, including the lungs. Because lefamulin is metabolized in the liver by CYP3A4, patients receiving this medication should be screened for drug-drug interactions. Less than 15% is excreted unchanged in the urine. Thus, no dosage adjustment is needed in kidney disease. Patients with liver disease do require a dose reduction.

CLINICAL USES

Lefamulin is noninferior to moxifloxacin for the treatment of community-acquired bacterial pneumonia.

ADVERSE EFFECTS

Lefamulin prolongs the QT interval and should be avoided in patients with preexisting prolonged QT or ventricular arrhythmias and in patients taking other QT-prolonging agents. The most common adverse effects with the oral formulation are GI (eg, diarrhea, nausea, and vomiting). Administration site reactions, such as pain and phlebitis, have been reported with the intravenous formulation. Lefamulin may also cause elevations in hepatic enzymes.

e1-10

Antituberculous Medications

Katherine Gruenberg
Emily Kaip

Mycobacteria are intracellular, have long periods of metabolic inactivity, and tend to develop resistance to treatment with only one medication. Therefore, *combined medication therapy is used to delay the emergence of resistance.* First-line medications used together in the treatment of tuberculosis include **isoniazid, ethambutol, rifampin**, and **pyrazinamide.** A regimen of **rifapentine, isoniazid, pyrazinamide,** and **moxifloxacin** has emerged as an alternative option for drug-susceptible tuberculosis. Regimens should be selected based on several factors including but not limited to susceptibility testing, drug interactions, and comorbidities. In select situations, directly observed therapy (DOT) may be helpful to ensure patient adherence.

See Chapter 9 for a discussion of these medications in pulmonary disease.

Dorman SE et al. Four-month rifapentine regimens with or without moxifloxacin for tuberculosis. N Engl J Med. 2021;384:1705. [PMID: 33951360]

Alternative Medications in Tuberculosis Treatment

Katherine Gruenberg
Emily Kaip

e1-11

The medications or medication classes listed alphabetically below are usually considered only in cases of drug resistance (clinical or laboratory) to first-line medications.

Bedaquiline, a mycobacterial ATP synthase inhibitor, is given as an oral tablet once daily for the treatment of multidrug-resistant tuberculosis. Bedaquiline has two black box warnings for QT prolongation and increased mortality compared with placebo in one study. Subsequent post-marketing studies have *not* confirmed these high mortality rates and *bedaquiline is considered a first-line agent for the treatment of multidrug-resistant tuberculosis.*

Clofazimine is a phenazine dye used in the treatment of leprosy and is active in vitro against both nontuberculous *Mycobacteria* (eg, *M avium* complex, *M kansasii*, etc) and *Mycobacterium tuberculosis.* It is given orally as a single daily dose of 100 mg for treatment of *M avium* complex disease. With limited clinical efficacy data, its use for the therapy of tuberculosis is reserved for multidrug-resistant *M tuberculosis*. Adverse effects include nausea, vomiting, abdominal pain, and skin discoloration.

Cycloserine, a bacteriostatic agent, is given in doses of 250–750 mg orally daily. It is effective for the treatment of highly resistant *M tuberculosis*, but it can induce a variety of CNS dysfunctions and psychotic reactions.

Ethionamide, like cycloserine, is bacteriostatic and is given orally in a dose of 15–20 mg/kg/day (maximal dose 1 g). It has been used in combination therapy but is poorly tolerated with marked gastric irritation and minimal efficacy has been demonstrated when used to treat multidrug-resistant *M tuberculosis*. Therefore, ethionamide is not recommended for the treatment of multidrug-resistant *M tuberculosis* when other more effective and better tolerated medications are available.

The **fluoroquinolones**, particularly moxifloxacin, are active in vitro against *M tuberculosis.* A 4-month moxifloxacin-based regimen (moxifloxacin, rifapentine, isoniazid, and pyrazinamide for 8 weeks followed by 9 weeks of rifapentine, isoniazid, and moxifloxacin) is an option for patients older than 12 years with susceptible *M tuberculosis* pulmonary infection. Levofloxacin (750–1000 mg daily) and moxifloxacin (400 mg) can also be considered as treatment options for multidrug-resistant tuberculosis. The WHO has recently endorsed the use of a 6-month regimen containing bedaquiline, pretomanid, linezolid, and moxifloxacin (BPaLM) in patients with multidrug-resistant tuberculosis with rifampin resistance.

Linezolid is effective in achieving culture conversion in patients with treatment-refractory, highly resistant pulmonary tuberculosis. However, the long-term use of this agent for tuberculosis is associated with bone marrow toxicity and neuropathy, particularly at doses of 600 mg daily.

Pretomanid targets both active and inactive *M tuberculosis* via inhibition of mycolic acid biosynthesis in actively dividing strains and generation of toxic nitric oxide in dormant strains under anaerobic conditions. Pretomanid was approved as a once-daily oral tablet (200 mg) given in combination with bedaquiline and linezolid for the treatment of drug-resistant tuberculosis. Pretomanid carries several warnings for hepatotoxicity, lactic acidosis, myelosuppression, peripheral and optic neuropathy, reproductive toxicity, and QT prolongation.

e1-12

Rifamycins

Katherine Gruenberg
Emily Kaip

In addition to its use as a primary agent in the treatment of active and latent tuberculosis, **rifampin** is used as an adjunct in the treatment of *S aureus* infections. When used as monotherapy, rifampin is associated with rapid emergence of resistance in staphylococci. However, when added to other primary antistaphylococcal agents, rifampin improves outcomes in the treatment of infected prosthetic hardware. Due to its rapid bactericidal activity, rifampin was hypothesized to be an effective adjunct in the treatment of *S aureus* bacteremia without hardware present. However, the addition of rifampin to standard therapy for the treatment of *S aureus* bacteremia does *not* improve outcomes, including treatment failure, recurrence, or death.

Rifaximin, a derivative of rifamycin, is *nonabsorbable*, reaches very high levels in the stool, and has a broad spectrum of antibacterial activity, including aerobic and anaerobic gram-positive and gram-negative organisms. It is approved for use in nonpregnant individuals and for persons aged 12 years or older to treat noninvasive traveler's diarrhea (200 mg three times daily for 3 days) but should *not* be used if fever or bloody diarrhea is present. Rifamycins consistently display potent in vitro activity against *C difficile*, and small studies suggest rifaximin is useful, particularly following a course of oral vancomycin in the treatment of patients with recurrent disease. Other potential uses include prophylaxis of traveler's diarrhea (200 mg/day) and therapy of hepatic encephalopathy (550 mg twice daily). Rifaximin is also approved for the treatment of irritable bowel syndrome without constipation in adults. It is well tolerated and safe.

Rifapentine, a long-acting rifamycin, in combination with isoniazid, can be administered once weekly for 12 weeks in the treatment of latent tuberculosis. Although previously considered the gold standard for latent tuberculosis, the WHO considers 9 months of isoniazid monotherapy to be equivalent to 3 months of rifapentine with isoniazid. Even under directly observed treatment, completion of treatment is more likely with the short course of rifapentine with isoniazid compared with longer courses of isoniazid monotherapy. Rifapentine is included as a treatment option in a 4-month regimen (moxifloxacin, rifapentine, isoniazid, and pyrazinamide for 8 weeks followed by 9 weeks of rifapentine, isoniazid, and moxifloxacin) for patients older than 12 years with susceptible *M tuberculosis* pulmonary infection.

Rifabutin is generally thought to cause cytochrome P450 enzyme induction to a lesser degree than rifampin and may be substituted in clinical practice when drug-drug interactions preclude the use of rifampin. Rifabutin is a second-line agent for *M avium* complex prevention in persons living with advanced HIV who are not receiving fully suppressive antiretroviral therapy and have CD4 count < 50 cells/mm^3. Rifabutin can also be considered as a third drug for the treatment of disseminated *M avium* complex disease in combination with either clarithromycin or azithromycin and ethambutol in patients with high mycobacterial loads or lacking effective HIV antiretroviral therapy. Rifabutin may also be included in treatment regimens for active *M tuberculosis* infections and latent tuberculosis in select patients. Rifabutin-containing regimens have also shown promise in the treatment of *H pylori* infections, and the combination of a PPI, amoxicillin, and rifabutin is now endorsed as a first-line therapy for both treatment-naïve patients and treatment-experienced patients with refractory infection after receiving bismuth quadruple therapy.

Sulfonamides & Antifolate Medications

e1-13

Katherine Gruenberg
Emily Kaip

ANTIMICROBIAL ACTIVITY

Sulfonamides are structural analogs of *p*-aminobenzoic acid (PABA) and compete with PABA to block its conversion to dihydrofolic acid. Organisms that utilize PABA in the synthesis of folates and pyrimidines are inhibited. Animal cells and some resistant microorganisms (eg, enterococci) use exogenous folate and thus are not affected by sulfonamides.

Trimethoprim and **pyrimethamine** are compounds that inhibit the conversion of dihydrofolic acid to tetrahydrofolic acid by blocking the enzyme dihydrofolate reductase. These two agents are generally used in combination with other medications (usually sulfonamides) to prevent or treat several bacterial and parasitic infections. At high doses, pyrimethamine can cause clinically significant inhibition of mammalian dihydrofolate reductase, causing bone marrow suppression. *Folinic acid (leucovorin) is given concurrently with pyrimethamine to prevent bone marrow suppression.*

Sulfonamides alone are rarely used in the treatment of bacterial infection. When used in combination with other medications, sulfonamides are useful in the treatment of toxoplasmosis and pneumocystosis.

The combination of trimethoprim (one part) plus sulfamethoxazole (five parts) is bactericidal for *E coli*, *Klebsiella*, *Enterobacter*, *Salmonella*, and *Shigella*, though substantial resistance has emerged with all these organisms. It is also active against many strains of *M catarrhalis*, *H influenzae*, *L monocytogenes*, *Serratia*, *Providencia*, *S maltophilia*, *B cepacia* (formerly *Pseudomonas cepacia*), and *Burkholderia pseudomallei*, but not against *P aeruginosa*. It is inactive against anaerobes and enterococci but inhibits most *Nocardia* and *S aureus* (including MRSA), but retains activity against fewer *S epidermidis* isolates.

PHARMACOKINETICS & ADMINISTRATION

Trimethoprim-sulfamethoxazole is well absorbed from the GI tract and widely distributed in tissues and fluids, including CSF, achieving similar serum levels with either intravenous or oral administration. Dosage adjustment is required for kidney disease (creatinine clearance 50 mL/min or less).

CLINICAL USES

A. Urinary Tract Infections

Coliform bacteria, the most common cause of UTIs, are moderately inhibited by sulfonamides. However, resistance of *E coli* to sulfonamides is common and *IDSA cautions against using them empirically in communities with high (defined as > 20%) rates of resistance*. Since trimethoprim is concentrated in the prostate, trimethoprim-sulfamethoxazole, one double-strength tablet twice daily for 14–21 days, is effective in acute prostatitis due to susceptible pathogens. In chronic prostatitis, treatment for 6–12 weeks is indicated.

B. Parasitic Infections

Trimethoprim-sulfamethoxazole is effective for prophylaxis and treatment of pneumonia due to *Pneumocystis jirovecii* and treatment of *Cyclospora* infection and *Cystoisospora belli* infection. For therapy of *Pneumocystis* pneumonia, 15 mg/kg/day of trimethoprim (with the associated 75 mg/kg/day of sulfamethoxazole) in three or four divided doses is administered intravenously or orally—depending on the severity of disease—for 3 weeks. The dose for prophylaxis is 160 mg of trimethoprim plus 800 mg of sulfamethoxazole daily or three times per week. (When given daily, it is also effective prophylaxis against *Toxoplasma* encephalitis.) *C belli* infection in HIV/AIDS has been successfully treated with 160 mg of trimethoprim plus 800 mg of sulfamethoxazole orally four times daily for 10 days. Cyclosporiasis is successfully treated with 160 mg of trimethoprim and 800 mg of sulfamethoxazole twice daily for 7–10 days. Sulfadiazine with pyrimethamine is also used to treat and prevent recurrence of toxoplasmosis.

C. Other Bacterial Infections

Considering the frequent observation of CA-MRSA skin and soft tissue infection, trimethoprim-sulfamethoxazole is a potential option in the outpatient treatment of this pathogen. Trimethoprim-sulfamethoxazole is associated with a high cure rate among patients with a drained cutaneous abscess. However, increasing rates of trimethoprim-sulfamethoxazole resistant MRSA warrant close monitoring of local resistance patterns.

Trimethoprim-sulfamethoxazole is the medication of choice for *Nocardia* infections. Trimethoprim-sulfamethoxazole is widely distributed in tissues, penetrates into the CSF, and while occasionally used to treat meningitis caused by gram-negative rods, third-generation cephalosporins have greater clinical experience and are preferred agents.

Trimethoprim-sulfamethoxazole is also effective for infections with *Enterobacter, B pseudomallei* (melioidosis), *S maltophilia*, or *B cepacia;* in combination with rifampin for eradication of nasopharyngeal carriage of staphylococci; for *Pneumocystis* prophylaxis in organ and stem cell transplant recipients and persons living with HIV with CD4 counts < 200 cells/mcL; and as an option for treatment of *L monocytogenes* meningitis.

D. Leprosy

Certain sulfones are widely used (see below).

ADVERSE EFFECTS

A. Systemic Side Effects

Fever, skin rashes, urticaria; nausea, vomiting, or diarrhea; stomatitis, conjunctivitis, arthritis, aseptic meningitis, exfoliative dermatitis; bone marrow depression, thrombocytopenia, hemolytic anemia (in glucose-6-phosphate dehydrogenase [G6PD] deficiency) or aplastic anemia, granulocytopenia, leukemoid reactions; hepatitis, polyarteritis nodosa, vasculitis, Stevens-Johnson syndrome; reversible hyperkalemia; and many others have been reported. Patients with history of severe cutaneous adverse reactions (eg, Stevens-Johnson syndrome, acute generalized exanthematous pustulosis, drug reaction with eosinophilia and systemic symptoms, and toxic epidermal necrolysis) should *not* be re-challenged. However, guidelines recommend oral challenge for patients with history of non-severe or anaphylactic allergies; skin testing can also be done for patients with history of anaphylaxis with sulfonamide antimicrobials.

B. Urinary Tract Disturbances

Older sulfonamides were relatively insoluble and would precipitate in urine. The most commonly used sulfonamides presently (sulfamethoxazole) are quite soluble, and the old admonition to force fluids is no longer warranted. However, patients with toxoplasmosis receiving high-dose sulfadiazine, one of the older sulfonamides, commonly experience crystalluria. Sulfonamides are rarely associated with interstitial nephritis.

Drekonja DM et al. Effect of 7 vs 14 days of antibiotic therapy on resolution of symptoms among afebrile men with urinary tract infection: a randomized clinical trial. JAMA. 2021;326:324. [PMID: 34313686]

Ham DC et al. Trimethoprim-sulfamethoxazole resistance patterns among *Staphylococcus aureus* in the United States, 2012-2018. Infect Control Hosp Epidemiol. 2023;44:794. [PMID: 35166197]

Khan DA et al. Drug allergy: a 2022 practice parameter update. J Allergy Clin Immunol. 2022;150:1333. [PMID: 36122788]

Sulfones

Katherine Gruenberg
Emily Kaip

e1-14

A number of medications closely related to the sulfonamides (eg, **dapsone**) have been used effectively in the long-term treatment of leprosy. The clinical manifestations of both lepromatous and tuberculoid leprosy can often be suppressed by treatment extending over months to years. At least 5–30% of *Mycobacterium leprae* organisms are resistant to dapsone, so initial three-drug treatment with rifampin, dapsone, and clofazimine is advocated. Dapsone, 100 mg daily, is an alternative therapy option for mild to moderate *Pneumocystis* pneumonia in persons living with HIV when combined with trimethoprim, 15 mg/kg/day in three divided doses. Dapsone is an effective prophylactic agent against *P jirovecii* infection when dosed at 100 mg daily, 50 mg daily in combination with pyrimethamine 50 mg and leucovorin 25 mg weekly, or 200 mg once weekly in combination with pyrimethamine 75 mg and leucovorin 25 mg. Dapsone can also be used to prevent *Toxoplasma* encephalitis in patients with HIV when dosed 50 mg daily combined with pyrimethamine 50 mg and leucovorin 25 mg weekly.

ABSORPTION, METABOLISM, & EXCRETION

All sulfones are well absorbed from the intestinal tract, are distributed widely in all tissues, and tend to be retained in skin, muscle, liver, and kidney. Leprosy causes alterations in skin, which may influence how medications are absorbed and retained. Sulfones are excreted into the bile and reabsorbed by the intestine, prolonging therapeutic blood levels. Excretion into the urine is variable, and the medication occurs in urine mostly as a glucuronic acid conjugate.

DOSAGES & ROUTES OF ADMINISTRATION

See the section on Leprosy in Chapter 38-38 for recommendations.

ADVERSE EFFECTS

The sulfones may cause any of the side effects listed above for sulfonamides. *Considering that sulfones can be cross-reactive with sulfonamides, they should not be used in those patients experiencing significant sulfonamide adverse events*. Anorexia, nausea, and vomiting are common. Hemolysis, methemoglobinemia, or agranulocytosis may occur. G6PD status should always be determined prior to initiation of dapsone therapy. If sulfones are not tolerated, clofazimine can be substituted.

e1-15

Bacitracin, Mupirocin, Clindamycin, Metronidazole, Tinidazole, Vancomycin, & Bezlotoxumab

Katherine Gruenberg
Emily Kaip

1. Bacitracin

This polypeptide is selectively active against gram-positive bacteria. Because of severe nephrotoxicity associated with systemic administration, its use has been limited to topical application on surface lesions, sometimes in combination with polymyxin or neomycin.

2. Mupirocin

Mupirocin (formerly pseudomonic acid) is a naturally occurring antibiotic produced by *Pseudomonas fluorescens* active against most gram-positive cocci, including methicillin-sensitive *S aureus,* MRSA and most streptococci (but not enterococci). *Used topically, it can decolonize staphylococcal carriage after application to the anterior nares twice daily for 5 days.* Studies demonstrate an associated reduction in postoperative staphylococcal lung infections in colonized patients treated with mupirocin. However, recurrent colonization occurs (50% at the end of 1 year), and high rates of resistance have been observed in MRSA isolates, suggesting *the benefit of mupirocin is limited. The Society for Healthcare Epidemiology of America and Infectious Diseases Society of America recommend the use of mupirocin with chlorhexidine for MRSA decolonization.* Mupirocin is equal to oral β-lactams in the treatment of mild impetigo.

3. Clindamycin

Clindamycin is active against gram-positive organisms including *S pneumoniae*, viridans streptococci, group A streptococci, and *S aureus*, though resistance has been described in all these pathogens. Pneumococci or staphylococci with an efflux-based mechanism of resistance can be effectively treated with clindamycin. However, isolates with ribosomal methylase resistance can be expected to be resistant to clindamycin. Enterococci and most *S epidermidis* are resistant. Susceptibility of CA-MRSA isolates to clindamycin varies regionally. In those instances, in which CA-MRSA isolates demonstrate resistance to macrolides but susceptibility to clindamycin, additional microbiologic testing is advised to confirm the effectiveness of clindamycin. Clindamycin is as efficacious as trimethoprim-sulfamethoxazole in uncomplicated skin and soft tissue infection in emergency department patients. A dosage of 150–300 mg orally every 6 hours is generally given for bacterial infections. It is widely distributed in tissues but does not achieve therapeutic levels in CSF. Excretion is primarily nonrenal.

Clindamycin is recommended as an alternative medication for prophylaxis against endocarditis following certain dental procedures in patients allergic to amoxicillin. Clindamycin, 300 mg orally twice daily for 7 days, can be used as an alternative to metronidazole for the therapy of bacterial vaginosis. Topical application of a 2% vaginal cream once daily for 7 days or 100-mg ovules intravaginally once at bedtime for 3 days is also effective. Clindamycin is active against most anaerobes, including *Prevotella, Clostridium, Peptococcus, Peptostreptococcus*, and *Fusobacterium* organisms. However, up to 25% of *B fragilis* isolates are resistant, and alternative agents should be considered for serious infections due to these organisms. Clindamycin is effective in the treatment of staphylococcal osteomyelitis, particularly in children. Considering tissue models confirm that clindamycin significantly decreases toxin production, the addition of clindamycin to penicillin for treatment of group A *Streptococcus* toxic shock syndrome is recommended. The combination of clindamycin and vancomycin is associated with decreased length of stay and reduced hospital readmission rates, probably due to this reduction in toxin production. Clindamycin in combination with primaquine is an alternative in the treatment of *Pneumocystis* pneumonia. While useful in brain abscess, clindamycin is ineffective in meningitis.

Common side effects are diarrhea, nausea, and skin rashes. Antibiotic-associated colitis has been associated with the administration of clindamycin and other antibiotics and is due to a necrotizing toxin produced by *C difficile.* Interestingly, antecedent use of clindamycin is not a risk factor for the hypervirulent strain of *C difficile*.

4. Metronidazole & Tinidazole

Metronidazole is an antiprotozoal medication (see Chapter 40-07) also active against most anaerobic gram-negative bacilli (ie, *Bacteroides, Prevotella, Fusobacterium*) as well as *Clostridium* species but has minimal activity against many anaerobic gram-positive and microaerophilic organisms. It is well absorbed after oral administration and is widely distributed in tissues. It penetrates well into the CSF, yielding levels similar to those in serum. The medication is metabolized in the liver, and dosage reduction is required in severe hepatic insufficiency or biliary dysfunction. **Tinidazole** is identical in spectrum of activity to metronidazole.

Metronidazole is used to treat amebiasis and giardiasis (see Chapters 40-07 and 40-10) and in the following circumstances:

1. The nitroimidazoles are the only class of medications with clinically demonstrated efficacy against *T vaginalis* infections. Vaginitis caused by *Trichomonas* can be treated with metronidazole 500 mg orally two times daily for 7 days or a single 2 g dose of tinidazole. Men with trichomoniasis can be treated with metronidazole 2 g as a single dose. Bacterial vaginosis is treated with metronidazole 500 mg twice daily for 7 days. Metronidazole vaginal cream (0.75%) applied once daily for 5 days is also effective. Resistance with metronidazole is generally low level and can be treated with tinidazole. Metronidazole 500 mg every 12 hours is recommended in combination with ceftriaxone and doxycycline for the treatment of pelvic inflammatory disease.
2. In anaerobic infections, metronidazole can be given orally or intravenously, 500 mg two to three times daily. In contrast to clindamycin or cefoxitin and cefotetan, metronidazole is active against virtually all *B fragilis* isolates.
3. Metronidazole was previously recommended for treatment of mild *C difficile* colitis. However, multiple studies confirm its inferiority to other agents, and *metronidazole is no longer recommended as first-line treatment for this indication*. Intravenous metronidazole may be used in combination with enteral vancomycin (with or without rectally administered vancomycin) in the treatment of fulminant *C difficile* infection.
4. Therapy of brain abscess, often in combination with penicillin or a third-generation cephalosporin.
5. In combination with other agents in the treatment of *H pylori* infections.

Adverse effects include stomatitis, nausea, and diarrhea. Ingestion of alcohol while taking metronidazole occasionally results in a disulfiram reaction. Neurotoxicity manifesting as peripheral neuropathy or CNS abnormalities (ie, encephalopathy, ataxia) can develop, particularly with prolonged use at high doses. Metronidazole can decrease the metabolism of warfarin, necessitating dosage adjustment of warfarin.

Wiesenfeld HC. A randomized controlled trial of ceftriaxone and doxycycline, with or without metronidazole, for the treatment of acute pelvic inflammatory disease. Clin Infect Dis. 2021;72:1181. [PMID: 32052831]

5. Vancomycin

Vancomycin is bactericidal for most gram-positive organisms, particularly staphylococci and streptococci, but it is bacteriostatic for most enterococci. While active against staphylococci, vancomycin kills more slowly compared with nafcillin or cefazolin, and consequently, these β-lactams are preferred in the treatment of serious infection due to methicillin-susceptible *S aureus*. Although vancomycin has retained activity against staphylococci and streptococci, vancomycin-resistant strains of enterococci (particularly *E faecium*) are common. *S aureus* both intermediately sensitive and highly vancomycin-resistant has been observed in patients receiving long-term vancomycin therapy. *Vancomycin is not absorbed from the GI tract and thus useful orally only for the treatment of antibiotic-associated Clostridioides enterocolitis.* For systemic infection, vancomycin must be administered intravenously (15–20 mg/kg every 8 to 12 hours). A loading dose of 20 to 35 mg/kg (maximum loading dose 3,000 mg) may be given to seriously ill patients with invasive MRSA infections to quickly reach target concentrations. Vancomycin is excreted mainly via the kidneys. In ESKD, the half-life may extend to 8 days. Vancomycin is cleared via high-flux hemodialysis and continuous renal replacement therapy, resulting in the need for maintenance dosing in such patients. In patients with impaired kidney function, the dosing interval is determined by measuring serum levels. When trough serum levels decline to 10–15 mcg/mL or AUC values are < 400 mg × hour/L, repeat dosing is required, primarily in the treatment of severe infection. Large doses (4 g daily or more) and concomitant use of piperacillin-tazobactam have been associated with mild reversible nephrotoxicity. Vancomycin likely increases the risk of aminoglycoside-associated nephrotoxicity. Vancomycin efficacy correlates with pharmacokinetics/pharmacodynamics. Specifically, an area under the curve (AUC) divided by the MIC of between 400 and 600 (AUC/MIC: 400–600 mg × hour/L) has been associated with favorable outcomes in serious infection due to MRSA. Considering this relationship, the MIC is critical regarding the decision to use vancomycin; when the MIC is ≥ 2 mcg/mL (or ≥ 1.5 mcg/mL by E-test), alternatives to vancomycin (including daptomycin, linezolid, and other agents, depending on the site of infection) may be considered.

Indications for parenteral vancomycin include the following: (1) MRSA and methicillin-resistant *S epidermidis* infections; (2) serious infections (pneumonia, meningitis) due to β-lactam resistant *S pneumoniae*; (3) ampicillin-resistant *Enterococcus*; (4) other gram-positive infections or prophylaxis in patients with severe penicillin-allergy; and (5) multi-drug–resistant gram-positive infections, ie, *Corynebacterium jeikeium*. In *C difficile*–associated disease, vancomycin, 125 mg, is given orally four times daily. Oral doses in excess of 125 mg are not associated with improved outcomes in the treatment of this disease, although 500 mg orally four times daily is recommended in combination with intravenous metronidazole in fulminant disease. Fidaxomicin is recommended over vancomycin in the treatment of uncomplicated first-time *C difficile* enterocolitis.

Thrombophlebitis sometimes follows intravenous injection. Reversible ototoxicity rarely occurs; risk factors include concomitant administration with aminoglycosides or high-dose intravenous erythromycins. Vancomycin has been associated with nephrotoxicity, particularly in combination with other nephrotoxic medications such as aminoglycosides. Concomitant administration of vancomycin with piperacillin-tazobactam also increases the risk for nephrotoxicity although piperacillin/tazobactam rarely causes nephrotoxicity alone. Vancomycin doses of 4 g or greater daily and elevated trough levels are also associated with an increased incidence of mild nephrotoxicity. Rapid infusion or high doses (1 g or more) may induce diffuse hyperemia and hypotension. This can be avoided by extending infusions over 1–4 hours, decreasing the concentration of the drug in the intravenous bag, reducing the dose, or pretreating with a histamine antagonist such as diphenhydramine.

6. Bezlotoxumab

Bezlotoxumab is a monoclonal antibody approved for use in combination with standard antibacterial therapy (metronidazole, vancomycin, or fidaxomicin) in patients at high risk for *C difficile* recurrence. Bezlotoxumab binds to and neutralizes toxin B produced by *C difficile*; bezlotoxumab does not exert antibacterial activity. With a half-life of 19 days, bezlotoxumab is administered as a one-time intravenous infusion. Bezlotoxumab should be avoided in patients with a history of HF since these patients have been found to be more likely to develop HF with this agent. Other side effects of bezlotoxumab include nausea, pyrexia, and headache.

Oxazolidinediones

Katherine Gruenberg
Emily Kaip

e1-16

Oxazolidinediones represent a class of antibacterials including **linezolid** and **tedizolid.** These agents are primarily active against aerobic gram-positive pathogens, including penicillin-resistant pneumococci, methicillin-resistant staphylococci and enterococci (both *E faecalis* and vancomycin-sensitive and vancomycin-resistant *E faecium*), and mycobacteria. Linezolid is bacteriostatic against all these pathogens. Linezolid resistance has been isolated from enterococci, *S aureus,* and *S epidermidis*. The oral bioavailability of these medications is excellent, with serum levels approaching those observed with intravenous administration. The medications are eliminated primarily by nonrenal mechanisms, though about 30–50% of the total linezolid dose and 18% of tedizolid is excreted in the urine. Tedizolid is administered once daily, whereas linezolid requires twice-daily dosing (except for the treatment of tuberculosis, for which linezolid is dosed 600 mg once daily).

The primary toxicity is bone marrow suppression with long-term therapy, particularly the platelet and WBC lines. Other adverse effects include neuropathy and mitochondrial toxicity with long-term use. While tedizolid appears to differ from linezolid with respect to the incidence of bone marrow toxicity, trials with long-term therapy are lacking, though some case studies suggest tedizolid is well-tolerated for longer treatment durations. Linezolid is a mild MAO, and while concomitant use of serotonergic medications may rarely result in a serotonin syndrome, most patients can safely receive both agents together. Tedizolid does not interact with serotonergic agents. While linezolid is modestly superior to vancomycin in confirmed MRSA pneumonia, it offers little to no advantage in the empiric treatment of hospital-acquired or ventilator-associated pneumonia. Of particular concern are the increasing reports of linezolid-resistant *Enterococcus* and staphylococci, which reinforce that this agent should be used judiciously after confirming susceptibility.

e1-17

Daptomycin

Katherine Gruenberg
Emily Kaip

Daptomycin is a bactericidal lipopeptide with a spectrum of activity similar to linezolid. This spectrum includes methicillin-resistant staphylococci and VRE; however, MICs are much lower for the former than the latter. Daptomycin has poor oral bioavailability and thus is only available as a parenteral product. Its long pharmacologic half-life allows for once-daily dosing at 4–6 mg/kg every 24 hours in skin and soft tissue infection and 8–10 mg/kg, every 24 hours in the treatment of bacteremia and right-sided endocarditis); dosage adjustment is necessary in the presence of kidney disease. Doses up to 12 mg/kg are recommended by some experts for treatment of vancomycin-resistant *Enterococcus*. Daptomycin used in combination with ceftaroline has been shown to reduce rates of clinical failure in patients with complicated MRSA bacteremia. The primary adverse event associated with daptomycin is a reversible, dose-dependent myopathy observed with 7 days or more of therapy, particularly with concomitant statin use. Considering this complication, monitoring of serum creatine kinase levels is recommended, particularly in those patients receiving long-term therapy. Daptomycin cannot be used in the treatment of primary respiratory tract infection because pulmonary surfactant binds daptomycin, resulting in subtherapeutic free drug concentrations in pulmonary secretions.

Chuma M et al. Association between statin use and daptomycin-related musculoskeletal adverse events: a mixed approach combining a meta-analysis and a disproportionality analysis. Clin Infect Dis. 2022;75:1416. [PMID: 35262686]
Johnson TM et al. Combination ceftaroline and daptomycin salvage therapy for complicated methicillin-resistant *Staphylococcus aureus* bacteraemia compared with standard of care. Int J Antimicrob Agents. 2021;57:106210. [PMID: 33609718]

Telavancin, Dalbavancin, Oritavancin

e1-18

Katherine Gruenberg
Emily Kaip

Telavancin was the first approved lipoglycopeptide for the treatment of skin and soft tissue infection due to resistant gram-positive bacterial pathogens. It is indicated as an alternative to vancomycin in skin and soft tissue infection and hospital-acquired and ventilator-associated bacterial pneumonia due to *S aureus* (MRSA and MSSA), vancomycin-susceptible *E faecalis*, *S pyogenes, S agalactiae,* or *S anginosus* group. Telavancin displays concentration-dependent bactericidal killing and a 7.5-hour half-life and post-antibiotic effect of 4–6 hours allowing for once-daily dosing. Taste disturbance, nausea, headache, foamy urine, prolonged QT, and reversible kidney injury are the most commonly observed adverse events. *Telavancin has a boxed warning highlighting the increased mortality in patients with preexisting kidney dysfunction (creatinine clearance 50 mL/min or less) with hospital-acquired/ventilator-associated bacterial pneumonia. Nephrotoxicity and embryofetal toxicity are also listed as boxed warnings.* Similar to daptomycin and linezolid, telavancin is useful in the treatment of resistant bacterial infection as an alternative for patients who are intolerant of vancomycin. However, the increased mortality risk in certain patients suggests it should serve a secondary role in the treatment of serious gram-positive infection.

Dalbavancin is a longer acting lipoglycopeptide similar to telavancin with similar spectrum of activity but does *not* prolong the QT interval. The recommended dosage is 1000 mg administered once followed by 500 mg 1 week later; dosage reduction should take place for patients with creatinine clearance < 30 mL/min. In the treatment of acute bacterial skin and skin structure infection, a single intravenous 1500 mg dose of dalbavancin appears to be equal to the weekly administered medication. Dalbavancin has also shown efficacy and safety in the treatment of osteomyelitis at a dose of 1500 mg given once weekly for two doses, and case series have suggested dalbavancin may be effective for other bone/joint infections and endocarditis.

Oritavancin is also a lipoglycopeptide with a particularly long pharmacologic half-life, such that a single dose of 1200 mg is equal to vancomycin in the treatment of acute bacterial skin infections. Oritavancin is significantly more active than telavancin or dalbavancin against VRE. While all three of these lipoglycopeptides are useful in the treatment of acute skin and skin-structure infection, their role in the treatment of more serious infections is still being explored.

e1-19

Quinolones

Katherine Gruenberg
Emily Kaip

The quinolones are synthetic analogs of nalidixic acid with a broad spectrum of activity against many bacteria. The mode of action of all quinolones involves inhibition of bacterial DNA synthesis by blocking the enzyme DNA gyrase.

Ciprofloxacin, levofloxacin, gemifloxacin, and **moxifloxacin** have potent antibacterial activity throughout the blood and tissues. **Delafloxacin**, a novel fluoroquinolone, accumulates at acidic pH and may offer an advantage against intracellular infections, such as *M tuberculosis*.

ANTIMICROBIAL ACTIVITY

With some exceptions, the spectrum of activity is similar among the available agents. In general, these medications have moderate to excellent activity against Enterobacterales but are also active against other gram-negative bacteria such as *Haemophilus, Neisseria, Moraxella, Brucella, Legionella, Salmonella, Shigella, Campylobacter, Yersinia, Vibrio*, and *Aeromonas* organisms. Fluoroquinolone resistance to *E coli*, including ESBL-producing pathogens, has steadily increased, with many centers reporting up to 20–30% resistance. Ciprofloxacin, levofloxacin, and delafloxacin have activity against *P aeruginosa*, but resistance limits their utility against this pathogen. None of these agents have reliable activity against *S maltophilia* or *B cepacia* or against certain genital tract pathogens, such as *Mycoplasma hominis, U urealyticum*, and *Chlamydia*. *M tuberculosis* is sensitive to the quinolones, as is *M fortuitum* and *Mycobacterium kansasii*.

In general, the fluoroquinolones are less potent against gram-positive bacteria when compared with gram-negative organisms. The exception is delafloxacin, which shows enhanced activity against gram-positive organisms, including levofloxacin-nonsusceptible MRSA. Gemifloxacin, levofloxacin, and moxifloxacin also have excellent gram-positive activity, including against streptococci, pneumococci, *S aureus*, and *S epidermidis*, as well as some methicillin-resistant strains. However, the emergence of resistant strains of staphylococci, particularly with monotherapy, has limited the use of these medications in infections caused by these organisms. Use of fluoroquinolones to treat tuberculosis in South Africa has been associated with emergence of invasive disease due to levofloxacin-nonsusceptible *S pneumoniae*. *T pallidum* and *Nocardia* are resistant to all fluoroquinolones.

Moxifloxacin and delafloxacin demonstrate modest activity against many of the significant anaerobic pathogens, including *B fragilis* and mouth anaerobes, but only moxifloxacin is approved for the treatment of intra-abdominal infection. Moxifloxacin also provides the most reliable coverage of *M tuberculosis*.

PHARMACOKINETICS & ADMINISTRATION

After oral administration, the fluoroquinolones are well absorbed and widely distributed in body fluids and tissues and are concentrated intracellularly. Fluoroquinolones bind some heavy metals; thus, absorption is inhibited when administered concomitantly with iron, calcium, and other multivalent cations. Optimal oral bioavailability is achieved if fluoroquinolones are taken 1 hour before or 2 hours after meals. The serum half-life ranges from 4 hours (ciprofloxacin) to 12 hours (moxifloxacin). Most are eliminated via mixed renal and nonrenal pathways. As a result, only modest accumulation takes place in the presence of kidney disease. Exceptions are ofloxacin and levofloxacin, which are primarily dependent upon the kidney for elimination.

CLINICAL USES

While fluoroquinolones previously were considered medications of choice in the empiric treatment of uncomplicated UTI, *the IDSA recommends* ***against*** *using these agents as medications of choice for the treatment of UTI in women.* Fluoroquinolones are not recommended for the treatment of acute bacterial sinusitis; however, the "*respiratory fluoroquinolones*" (gemifloxacin, levofloxacin, moxifloxacin) are recommended by the IDSA for patients at high risk with community-acquired pneumonia. The respiratory fluoroquinolones are exquisitely active against the most common community-acquired pneumonia pathogens, including *S pneumoniae*, *H influenzae*, and the "atypical pathogens" (eg, *Legionella*, *Mycoplasma*, and *Chlamydophila pneumoniae*).

Quinolones have excellent penetration into prostatic secretions and are effective in the treatment of acute and chronic bacterial prostatitis due to susceptible pathogens.

Fluoroquinolones have been used successfully to treat complicated skin and soft tissue infections and osteomyelitis caused by gram-negative organisms. Ciprofloxacin, 500–750 mg orally twice daily for at least 6 weeks, has been effective in the treatment of malignant otitis externa.

While previously reliably active against *Campylobacter*, extensive fluoroquinolone resistance has resulted in macrolides replacing them as drugs of choice. However, fluoroquinolones are active against the other major bacterial pathogens associated with diarrhea (*Salmonella, Shigella, enterotoxigenic E coli*). Consequently, they have been used for the therapy of traveler's diarrhea as well as domestically acquired acute diarrhea.

Ciprofloxacin, similar to rifampin, has been used to eradicate meningococci from the nasopharynx of carriers.

Fluoroquinolones are effective for prophylaxis against gram-negative infections in the neutropenic patient; however, development of resistance is well-documented.

Although gemifloxacin, levofloxacin, and moxifloxacin are useful in the treatment of community-acquired pneumonia, their broad aerobic gram-negative spectrum and the rapid emergence of resistance suggests they should be reserved for the treatment of refractory infections or patients at high risk, including those with comorbidities or recent receipt of β-lactam antibacterials. One setting in which ciprofloxacin is indicated for the therapy of lower respiratory tract infections is in cystic fibrosis, in which *P aeruginosa* is the predominant pathogen. However, the increasing rate of pseudomonal resistance to ciprofloxacin and levofloxacin has diminished their utility for this indication.

ADVERSE EFFECTS

The most prominent adverse effects of the quinolones are nausea, vomiting, and diarrhea. Occasionally, headache, dizziness, seizures, insomnia, impaired liver function, and skin rashes have been observed as well as more serious reactions such as AKI, hypoglycemia (especially with gatifloxacin, which has been removed from the US market, and moxifloxacin), and anaphylaxis. *With the exception of delafloxacin, all fluoroquinolones likely prolong the QT interval;* it is unclear whether any one agent is implicated more than another. Quinolones should be used cautiously in patients with a history of prolonged QT or concomitant use of drugs known to prolong QT. Prolongation of the prothrombin time and the INR has been observed in some patients receiving stable doses of warfarin after ciprofloxacin has been given, but this interaction is unpredictable and modest. Tendinitis and tendon rupture have been reported with quinolone agents. Risk factors include concomitant corticosteroid use, age older than 60 years, kidney dysfunction, and organ transplant. *The FDA has required a black box warning for tendinopathy.* Patients experiencing musculoskeletal symptoms while receiving fluoroquinolones should discontinue therapy. In addition, *the FDA has issued warnings regarding peripheral neuropathy.* Its onset can be within a few days of initiation of therapy and can be permanent in some patients. Lastly, while rare, *fluoroquinolones are associated with an increased rate of aortic aneurysm and dissection,* and the FDA recommends against use of fluoroquinolones in patients at high risk for these complications, including older adult patients and those with a history of high blood pressure, vessel blockages, and other genetic disorders.

Choi S-H et al. Respiratory fluoroquinolone monotherapy vs. β-lactam plus macrolide combination therapy for hospitalized adults with community-acquired pneumonia: a systematic review and meta-analysis of randomized controlled trials. Int J Antimicrob Agents. 2023;62:106905. [PMID: 37385561]

Newton ER et al. Association of fluoroquinolone use with short-term risk of development of aortic aneurysm. JAMA Surg. 2021;156:264. [PMID: 33404647]

e1-20

Pentamidine & Atovaquone

Katherine Gruenberg
Emily Kaip

Pentamidine and **atovaquone** are antiprotozoal agents that are primarily used to treat *Pneumocystis* pneumonia. Pentamidine is discussed in Chapter 40-01. Atovaquone inhibits mitochondrial electron transport and probably also folate metabolism. The solid dosage form is poorly absorbed and should be given with food to maximize bioavailability. The suspension is significantly better absorbed and preferred especially in patients at high risk (those with diarrhea, malabsorption). It has moderate activity against *P jirovecii*. Its role is primarily for prophylaxis against *P jirovecii* at a dose of 1500 mg daily, but it can also be used as an alternative treatment option for patients with mild to moderate *P jirovecii* pneumonia who have not responded to or cannot tolerate other therapies at a dose of 750 mg orally twice daily. Major adverse effects include rash, nausea, vomiting, diarrhea, fever, and abnormal liver biochemical tests.

Urinary Antiseptics

Katherine Gruenberg
Emily Kaip

e1-21

These medications exert antimicrobial activity in the urine but have *little or no systemic antibacterial effect*. Their usefulness is limited to therapy and prevention of UTIs.

1. Nitrofurantoin

Nitrofurantoin is active against the common gram-positive urinary pathogens *E faecalis* and *Staphylococcus saprophyticus*, but the medication inhibits only about 50% of *E faecium*. While nitrofurantoin is active against *E coli* and *Citrobacter*, susceptibility against *Proteus, Serratia*, and *Pseudomonas* is poor. Considering its reliable activity against *E coli*, *nitrofurantoin is one of the primary options recommended by the IDSA for the treatment of UTI*. Following oral administration, about 50% of the medication is absorbed, but serum concentrations are very low and tissue levels are undetectable. Levels in the urine reach concentrations of 200–400 mcg/mL, which are well above the MICs of susceptible organisms. In kidney disease, previously defined as eGFR < 60 mL/min/1.73 m^2, subtherapeutic urine levels are present and medication accumulation takes place in serum. However, data suggest that nitrofurantoin is effective down to an eGFR of 30 mL/min/1.73 m^2. Given low serum levels, poor tissue penetration, and renal elimination, the use of nitrofurantoin is limited to therapy or prophylaxis of cystitis in patients with normal or moderately reduced kidney function. *Nitrofurantoin cannot be used to treat pyelonephritis or prostatitis.*

Depending on the formulation, the average daily dose in UTIs is 100 mg orally two to four times daily, taken with food. The macrocrystal preparation can be given at a dosage of 100 mg twice daily. A single daily dose of 50–100 mg can prevent recurrent UTIs in women.

Oral nitrofurantoin often causes nausea and vomiting. The crystalline formulation is better tolerated than previous preparations. Hemolytic anemia may occur in G6PD deficiency. Other side effects are skin rashes and, uncommonly, peripheral neuropathy. Acute and chronic pulmonary hypersensitivity reactions may occur, and pulmonary fibrosis has occurred with prolonged use.

2. Fosfomycin

Fosfomycin tromethamine is a phosphonic acid derivative useful in the treatment of uncomplicated UTI. The spectrum of activity includes *E coli*, including ESBL-producing isolates, *E faecalis*, and other gram-negative aerobic urinary pathogens, but not *P aeruginosa*. Considering the increased resistance associated with *E coli* in the treatment of UTI, fosfomycin has increased its utility in this disease state. Available as a 3-g sachet, fosfomycin may be useful for the single-dose treatment of the above organisms. Like nitrofurantoin, fosfomycin should not be used for systemic infection. Five days of nitrofurantoin are superior to single-dose fosfomycin in the treatment of uncomplicated lower UTI in healthy women. Although clinical experience is limited, the ability of fosfomycin to penetrate prostatic secretions may be sufficient to use in the treatment of bacterial prostatitis. Fosfomycin disodium is available in Europe for intravenous use and may be useful in the treatment of more serious infections. The most frequently reported adverse effects include diarrhea, headache, and nausea.

Doesschate TT et al. Fosfomycin vs ciprofloxacin as oral step-down treatment for *Escherichia coli* febrile urinary tract infections in women: a randomized, placebo-controlled, double-blind, multicenter trial. Clin Infect Dis. 2022;75:221. [PMID: 34791074]

e1-22

Antifungal Medications

Katherine Gruenberg
Emily Kaip

Empiric antifungal therapy is primarily reserved for immunocompromised (eg, hematologic malignancy or solid organ transplant) and other patients at high risk (eg, patients receiving total parenteral nutrition or prolonged broad-spectrum antibiotics). When yeast or mold is seen on KOH preparation test or when isolated organisms are thought to be pathogenic, antifungal therapy may also be initiated. Antifungal standardized susceptibility testing is available for *Candida* spp and predicts clinical outcome. In contrast, susceptibility testing for most other fungi is only available at certain centers; in vitro results for these pathogens are less predictive of patient outcomes due to limited clinical experience.

1. Amphotericin B

Amphotericin B is a broad-spectrum agent active against *Aspergillus, Histoplasma, Cryptococcus, Coccidioides, Candida, Blastomyces, Sporothrix, Mucor*, among others. *Pseudallescheria boydii* and *Fusarium* are often resistant to amphotericin B.

LIPID-BASED AMPHOTERICIN B

The nephrotoxicity of conventional amphotericin has resulted in the development of lipid-based amphotericin B, which has been associated with less nephrotoxicity and infusion reactions when compared with conventional amphotericin B. The most commonly used agent is **liposomal amphotericin B** (L-AmB; AmBisome). Liposomal amphotericin B 10 mg/kg/day is generally not more efficacious, but more nephrotoxic, than 3 mg/kg/day in the treatment of invasive mold infection. The most common dose in the treatment of invasive aspergillosis is 5 mg/kg daily. Liposomal amphotericin B is effective in the treatment of visceral leishmaniasis using short courses (5–10 days) with low doses (2–4 mg/kg/day depending on which preparation is used), probably because of its distribution to the reticuloendothelial system, the major site of parasite invasion.

CONVENTIONAL AMPHOTERICIN B

The availability of lipid-based amphotericin, echinocandins, and triazoles has resulted in a greatly reduced role for conventional amphotericin for the prevention and treatment of fungal infection. The exception is treatment of neonatal candidiasis and symptomatic *Candida* cystitis, where conventional amphotericin B deoxycholate is preferred. If conventional amphotericin B is used, the daily dose for most fungal infections varies from 0.3 mg/kg to 0.7 mg/kg, although infections caused by *Aspergillus* and *Mucor* are often treated with 1–1.5 mg/kg daily.

Electrolyte disturbances (hypokalemia, hypomagnesemia, distal renal tubular acidosis) also commonly occur. Kidney injury can be reduced with sodium supplementation and intravenous hydration.

2. Nystatin

Nystatin has a wide spectrum of antifungal activity but is used almost exclusively to treat *superficial* candida infections. It is too toxic for systemic administration, and the medication is not absorbed from mucous membranes or the GI tract. Several preparations are available, including oral suspension (100,000 U/mL) and ointments, gels, and creams (100,000 U/g). For oral candidiasis, 500,000 units of suspension are used as a "swish and swallow" and repeated four times a day for at least 2 days after resolution of the infection. Infections of skin are treated with cream or ointment with 100,000 units applied to the affected area twice daily until resolution of the infection.

3. Flucytosine

Flucytosine inhibits some strains of *Candida*, *Cryptococcus*, and other fungi. Dosages of 3–8 g daily (75–150 mg/kg/day) orally produce therapeutic levels in serum, urine, and CSF. When used as monotherapy, development of resistance is common; thus, flucytosine is not used as a single medication therapy except in candiduria. In kidney disease, flucytosine may accumulate to toxic levels, and dosage adjustment is needed. The medication is effectively removed by hemodialysis. Toxic effects include bone marrow depression, abnormal liver function, and nausea. Combination amphotericin and flucytosine is associated with improved survival in patients with cryptococcal meningitis.

4. Natamycin

Natamycin is a polyene antifungal medication effective against many different fungi in vitro. When it is combined with appropriate surgical measures, topical application of 5% ophthalmic suspension may be beneficial in the treatment of keratitis caused by *Fusarium*, *Acremonium* (cephalosporium), or other fungi. The toxicity after topical application appears to be low.

5. Terbinafine

Terbinafine, an allylamine, inhibits fungal cell membrane function by blocking ergosterol synthesis. Terbinafine is available topically as well as in 250-mg tablets for oral administration. It is superior to all other oral agents at a recommended dosage of 250 mg daily for 12 weeks for toenail infections and 250 mg daily for 6 weeks for fingernail infections. The medication also is active against many strains of *Candida* and *Aspergillus* organisms and has been used in combination with other antifungals to treat severe infections with these pathogens and others. Most adverse effects are minor (diarrhea, dyspepsia) or transient (taste disturbance). Rare cases of severe hepatic injury have occurred.

6. Antifungal Imidazoles & Triazoles

These antifungal medications inhibit synthesis of ergosterol, resulting in inhibition of membrane-associated enzyme activity, cell wall growth, and replication.

Clotrimazole, taken orally in the form of 10-mg troches five times daily, can prevent and treat oral candidiasis. Vaginal azole tablets for 1–7 days are effective for vaginal candidiasis. Topical preparations for treatment of cutaneous dermatophytes are also available.

Fluconazole, a bis-triazole with activity similar to ketoconazole, is water-soluble and can be given both orally and intravenously. The medication is effective primarily in the treatment of *Candida, Cryptococcus*, and *Blastomyces* infections. *C albicans, C tropicalis*, and *C parapsilosis* are usually sensitive to fluconazole, but many other species of *Candida* (*C krusei, C glabrata*, etc) are often resistant. Fluconazole-resistant strains of *C albicans* are primarily observed in patients receiving long-term fluconazole therapy. *Candida auris*, closely related to *C krusei* and *C lusitaniae*, is commonly fluconazole resistant. *C auris has emerged as a global health threat due to its propensity to cause nosocomial outbreaks and its multidrug resistance* (voriconazole, amphotericin B, echinocandins). Fluconazole is inactive against *Aspergillus, Mucor*, and *Pseudallescheria*. Fluconazole is effective in oropharyngeal candidiasis and candidal esophagitis. A single oral dose of 150 mg is as effective or more effective than vaginal creams and suppositories in vaginal candidiasis. Fluconazole, 400 mg intravenously and orally daily, is as effective as amphotericin B, 0.5–0.6 mg/kg/day, for candidemia in both neutropenic and nonneutropenic patients. Fluconazole (200 mg/day), which penetrates well into the CSF, is effective as long-term suppressive therapy of cryptococcal meningitis in patients with HIV. In the treatment of cryptococcal meningitis, response rates and overall mortality rates are the same in patients treated with oral fluconazole and with amphotericin B. However, the mortality rate in the first 2 weeks is higher with fluconazole, and sterilization of CSF is slower with fluconazole. Consequently, cryptococcal meningitis induction therapy generally takes place with amphotericin B (in combination with flucytosine) for 2 weeks, followed by oral fluconazole. At a dose of 400 mg daily, fluconazole is effective therapy for coccidioidal meningitis (80% response), but improvement is slow, taking as long as 4–8 months. Increased doses (800–1200 mg/day) have been used in the treatment of coccidioidomycosis; however, they have not been found to be superior to usual doses. Fluconazole, 400 mg daily, is effective prophylaxis against superficial and invasive fungal infections in bone marrow and liver transplant recipients, but this practice results in superinfection with resistant organisms (*C krusei, C glabrata).* Increased doses of fluconazole may be necessary to achieve adequate drug exposure in critically ill pediatric cancer patients. Fluconazole is also effective for the therapy of cutaneous leishmaniasis due to *Leishmania major* in a dose of 200 mg/day for 6 weeks.

Fluconazole is well absorbed after oral administration (> 90% bioavailability, independent of meals), and serum levels approach those seen after administering the same dose intravenously. Thus, unless the patient cannot take medication by mouth or is hemodynamically unstable, the preferred route of administration is by mouth. While generally well tolerated, fluconazole is associated with dose-dependent nausea and vomiting. Altered liver biochemical tests (ALT, AST) and clinical hepatitis have been reported. Long-term use of fluconazole has also been associated with xerosis, alopecia, and fatigue. While less potent than other azoles (isavuconazole, itraconazole, ketoconazole, posaconazole, voriconazole), fluconazole inhibits cytochrome P450, resulting in reduced elimination of certain agents. Rifampin and phenytoin increase metabolism of fluconazole, necessitating increased fluconazole dosage.

Itraconazole is an oral triazole with variable bioavailability. It is moderately well absorbed from the GI tract (food increases absorption from 30% to 60%; antacids, PPIs, and H_2-receptor antagonists decrease absorption). While the tablet formulation should be administered with food, the solution is best absorbed on an empty stomach. A SUBA-itraconazole (super bioavailability itraconazole) formulation was developed to improve oral bioavailability and increase the GI tolerability of itraconazole. Itraconazole is widely distributed in tissues with the notable exception of the CNS, where levels in CSF are undetectable. Itraconazole solution is more predictably absorbed than the tablets. The medication is metabolized by the liver, and no dosage adjustment is needed in kidney disease. Itraconazole is very active against most strains of *Histoplasma capsulatum, Blastomyces dermatitidis, Cryptococcus neoformans, Sporotrichum schenkii*, and various dermatophytes. It is also active against *Aspergillus* species but inactive against *Fusarium* and *Zygomycetes.* Itraconazole in doses of 200–400 mg/day is effective and approved therapy for localized or disseminated histoplasmosis. It is also effective in sporotrichosis, dermatophytic infections (including those of the nails), and oral and esophageal candidiasis. Itraconazole is at least as effective as fluconazole in the treatment of nonmeningeal coccidioidomycosis and may be superior in the management of skeletal disease. At doses of 200 mg twice daily, itraconazole increases exercise tolerance and decreases corticosteroid requirements in patients with allergic bronchopulmonary aspergillosis. Itraconazole 200 mg once daily for 6 weeks (fingernail) or 12 weeks (toenail), or pulse therapy with 200 mg twice daily for 1 week each month, repeated for two months (fingernail) or 3 months (toenail), is effective in the treatment of onychomycosis for patients unable to take preferred agents.

Adverse effects are similar to fluconazole, with anorexia, nausea, vomiting, and abdominal pain occurring most commonly. Skin rash has been reported in up to 8% of patients. Hepatitis and hypokalemia occur uncommonly. Medications that induce hepatic cytochrome P450 (rifampin, phenytoin, phenobarbital) may increase itraconazole metabolism, and increased doses may be needed when these medications are administered concurrently with itraconazole. Itraconazole decreases the metabolism of cyclosporine, digoxin, and warfarin and also prolongs the QT interval, particularly in combination with other QT-prolonging medications. The usual dosage varies depending on the formulation and indication.

Voriconazole is a triazole antifungal with broad in vitro activity against most species of *Candida* and molds (eg, *Aspergillus, Fusarium, Pseudallescheria*, and others). It is as efficacious as liposomal amphotericin in the therapy of documented and suspected fungal infections in febrile neutropenic patients and superior to liposomal amphotericin in preventing breakthrough fungemia in this patient population. Voriconazole is superior to conventional amphotericin in the treatment of disseminated aspergillosis. Animal data also suggest voriconazole to be the most effective agent against *Aspergillus*, particularly in combination with caspofungin or another echinocandin. Voriconazole is the empiric drug of choice in the treatment of *Fusarium* and *Scedosporium* infections. Voriconazole is widely used in the treatment of neutropenic patients with suspected or documented fungal infection. Voriconazole has limited activity against zygomycete pathogens, and some centers have reported increased rates of infection due to *Rhizopus* and *Mucor* in stem cell transplantation patients receiving voriconazole. Similar to fluconazole, oral administration leads to predictable absorption.

The primary early toxicity associated with voriconazole is infusion-related and transient visual disturbances, particularly during the first week of therapy. *Of all the azole antifungal agents, voriconazole is associated with the most frequent elevation in liver biochemical tests and frank hepatitis.* Long-term therapy may be associated with a multistep phototoxic process, followed by actinic keratosis, then squamous cell carcinoma. It has been recommended that discontinuation of voriconazole take place in patients experiencing chronic photosensitivity. The trifluorinated molecular structure of voriconazole has been associated with increased fluoride levels and periostitis in patients receiving voriconazole for long-term therapy. When voriconazole is administered intravenously, it must be delivered in a cyclodextrin solution, which accumulates in kidney disease and has been associated with kidney toxicity in animal models. However, in human patients with kidney dysfunction, administration of voriconazole in cyclodextrin has *not* been associated with worsening kidney function. Similar to itraconazole, voriconazole is associated with numerous drug interactions. Enzyme inducers can decrease voriconazole plasma levels with potential for reduction in efficacy. Pharmacogenomic differences in cytochrome P450 2C19 can result in large differences in voriconazole clearance; therapeutic trough levels should be 1–5 mcg/mL. Voriconazole is also an inhibitor of cytochrome P450 activity, reducing the clearance of numerous substrates, including cyclosporine and tacrolimus, and can prolong the QT interval.

Posaconazole is an antifungal derivative of itraconazole with similar spectrum of activity as voriconazole, including yeast and *Aspergillus* spp. Unique from voriconazole, posaconazole has activity against the zygomycete fungi approaching that of amphotericin. Salvage treatment studies demonstrate efficacy in the treatment of these pathogens. Posaconazole is superior to fluconazole as fungal prophylaxis of neutropenia and noninferior to voriconazole for the treatment of invasive aspergillosis. The posaconazole delayed-release tablet is associated with improved oral bioavailability when compared with the oral solution. As a result, these dosage forms are not interchangeable on a mg-to-mg basis. Oral posaconazole suspension should be administered with a meal, but the delayed-release tablet may be administered with or without food. Intravenous posaconazole should be used in patients unable to tolerate oral therapy or at risk for malabsorption from the GI tract. Similar to voriconazole, posaconazole is primarily eliminated via nonrenal mechanisms. As with the other azole agents, posaconazole has primarily upper GI adverse events and occasional liver biochemical test abnormalities. While not as problematic as voriconazole, posaconazole is also an inhibitor of cytochrome P450 and can prolong the QT interval. Higher concentrations of posaconazole have been associated with pseudohyperaldosteronism.

Isavuconazole, the most recently approved azole, demonstrates excellent in vitro activity against both yeast and molds, including *Aspergillus* and the Mucorales. The medication is administered as the prodrug, isavuconazonium, which is available both as a highly absorbed oral preparation and a cyclodextrin-free intravenous formulation. Isavuconazole is at least as effective as voriconazole in the treatment of invasive mold infection due to *Aspergillus* and other filamentous fungi and much better tolerated. However, isavuconazole is less effective than caspofungin in the treatment of patients with invasive candidiasis. The rate of hepatobiliary, ocular, and skin disorders is significantly less with isavuconazole than with voriconazole. Isavuconazole is both a sensitive substrate and a mild to moderate inhibitor of CYP 3A4. Unlike the other azoles, isavuconazole has been associated with a shortened QT interval. Medications that alter gastric pH do not alter the oral bioavailability of the drug, and the oral preparation does not have dietary requirements.

Oteseconazole is an azole antifungal approved for the prevention of recurrent vulvovaginal candidiasis, including > 4 episodes within 12 months. For this indication, oteseconazole can either be taken alone for 12 weeks or in combination with fluconazole for a total of 14 weeks.

Oteseconazole is active against a variety of *Candida* spp including *C glabrata* and *C krusei*. Populations that should not take oteseconazole include persons of reproductive potential and those who are pregnant, lactating, or have moderate-severe hepatic or severe renal impairment. Absorption increases when oteseconazole is taken with a high fat and caloric meal. Oteseconazole does not appear to be affected by CYP450 inhibitors or inducers, but it does inhibit BCRP and should be used in caution with BCRP substrates (eg, rosuvastatin). Oteseconazole is well tolerated with the most frequent adverse effects reported being nausea and headache.

Ketoconazole, the first orally bioavailable azole, previously was used in the treatment of a variety of fungal infections. However, the improved spectrum of activity, reduced toxicity, and superior pharmacokinetics of newer azoles have reduced ketoconazole to a secondary role.

7. Echinocandins

The echinocandins (**anidulafungin, caspofungin, micafungin, rezafungin**) act by inhibiting fungal cell wall synthesis. They are active against *Candida*, including nonalbicans species, as well as *Aspergillus* species. They are not active against *Cryptococcus* or *Fusarium*. While appreciable in vitro activity against *Mucor* is lacking, clinical data suggest echinocandins are beneficial in combination with mold-active agents such as amphotericin B. Their long pharmacologic half-life confers the advantage of once-daily dosing; the exception being rezafungin, which is only dosed once weekly. No change in dose is necessary in patients with kidney disease; however, moderate to severe hepatic disease necessitates a reduction in dosage for caspofungin. Because dexamethasone, rifampin, and phenytoin significantly increase the metabolism of caspofungin, increased doses of the antifungal are necessary when these agents are given concomitantly. Animal data suggest that caspofungin is inferior to voriconazole in the treatment of *Aspergillus;* however, the addition of caspofungin to voriconazole has been associated with in vitro and in vivo additive or synergistic effects. Caspofungin is superior to conventional amphotericin B in the treatment of candidemia, primarily based on greater patient tolerability. The echinocandins should be considered the empiric medications of choice in the treatment of infections due to *C glabrata* and *C krusei* and possibly *C auris*. While these agents are generally active against *C glabrata*, the rate of resistance associated with echinocandins has increased over the past several years, now averaging 5–10%. Consequently, *all bloodstream infection isolates should be checked for echinocandin susceptibility*. Risk factors for echinocandin nonsusceptibility include prior echinocandin exposure, previous candidemia, recent hospitalization, and fluconazole resistance. Micafungin is as effective as and less toxic than liposomal amphotericin in the treatment of candidemia and invasive candidiasis. Anidulafungin is at least as effective as fluconazole in the treatment of invasive candidiasis. Empiric micafungin treatment in nonneutropenic critically ill patients does not increase fungal infection-free survival. Rezafungin, a second-generation echinocandin, is noninferior to caspofungin for the treatment of candidemia and invasive candidiasis.

These agents are associated with minimal toxicity or adverse effects. Histamine release is common with basic polypeptide compounds, such as the echinocandins; thus infusion-related reactions have been reported and can be mitigated by slowing the infusion rate.

8. Ibrexafungerp

Ibrexafungerp is a triterpenoid antifungal medication that also inhibits fungal cell wall synthesis. This orally available medication is active against multiple *Candida* species, including *C auris*, and *Aspergillus* species. Ibrexafungerp also retains activity against some azole-resistant and echinocandin-resistant *Candida* species as well as azole-resistant *Aspergillus* species. Ibrexafungerp is approved for the treatment of vulvovaginal candidiasis, dosed 300 mg every 12 hours for two doses. Administering ibrexafungerp with a high-fat meal (800–1000 calories) improves its bioavailability. Because ibrexafungerp is a CYP3A4 substrate and a minor substrate of P-glycoprotein, it is recommended to avoid concomitant use with moderate-strong CYP3A4 inducers and strong CYP3A4 inhibitors. No dose adjustments are recommended in renal or hepatic impairment. Ibrexafungerp is well tolerated, with the most common adverse effects being GI (abdominal pain, diarrhea, and nausea). Ibrexafungerp carries an FDA black box warning for embryo-fetal toxicity. Use in pregnancy is contraindicated. Patients who may become pregnant should be screened prior to initiation of ibrexafungerp and must use effective contraception throughout therapy as well as 4 days after the last dose.

Schwebke JR et al. Ibrexafungerp versus placebo for vulvovaginal Candidiasis treatment: a phase 3, randomized, controlled superiority trial (VANISH 303). Clin Infect Dis. 2022;74:1979. [PMID: 34467969]

e1-23

Antiviral Medications

Katherine Gruenberg
Emily Kaip

Several compounds can influence viral replication and the development of viral disease. For current information about the treatment of SARS-CoV-2, see Chapter 37.

AGENTS FOR INFLUENZA & OTHER RESPIRATORY VIRAL INFECTIONS

Neuraminidase inhibitors, including **zanamivir** inhalation and **oseltamivir** tablets and suspension, are effective in the prevention and treatment of influenza A and B and are also active against the avian influenza virus. **Peramivir** is an intravenous neuraminidase inhibitor approved for the treatment of influenza. The majority of influenza A and B viruses tested for drug resistance have been susceptible to oseltamivir, zanamivir, and peramivir but resistant to the adamantanes (amantadine, rimantadine). Thus, choices for oral therapy center upon oseltamivir and zanamivir. Neuraminidase inhibitors should generally be administered soon (within 48 hours) after the onset of symptoms to be most effective, though observational studies suggest that hospitalized patients or those with severe disease may still benefit if treatment is started after 48 hours. Zanamivir inhalers are difficult to use for some patients, especially those with asthma and COPD, in whom bronchospasm has been reported.

GI adverse events are the most common side effects of oseltamivir. In addition, while cause and effect are not well-established, neuropsychiatric disorders, including suicidal ideation, have been associated with oseltamivir. Both medications are administered twice daily (oseltamivir 75 mg orally; zanamivir 10 mg inhalation) for 5 days when used for therapy). Both agents reduce the duration of symptoms by 1 day and viral shedding by 2 days. However, treatment of critically ill patients initiated within 5 days after symptom onset has been associated with *decreased mortality*. Both agents also effectively prevent disease in household contacts when administered prophylactically (oseltamivir, 75 mg orally once daily; zanamivir, 10 mg inhaled once daily) for 7 days. Critically ill patients, in most instances, are unable to receive antiviral agents via the oral or inhaled route of administration. Peramivir, an intravenous antiviral, is available as a single dose. It is as effective as, but more expensive than, oral oseltamivir. Peramivir is not recommended for influenza chemoprophylaxis due to lack of data for this indication.

Baloxavir marboxil is a small-molecule prodrug approved for the treatment of uncomplicated influenza and postexposure prophylaxis of influenza A or B. Baloxavir marboxil is hydrolyzed to an active form, baloxavir, which inhibits influenza polymerase acidic endonuclease to halt replication of influenza A and B. With this unique mechanism of action, baloxavir is not influenced by adamantane or neuraminidase resistance. However, resistance to baloxavir has been detected. Baloxavir marboxil is administered as a one-time, weight-based oral dose within the first 48 hours of symptom onset. This medication is approved for adults and pediatric patients aged 12 years or older and weighing 40 kg or more. When administered, baloxavir marboxil should be separated from polyvalent cations, such as calcium, magnesium, iron, etc. In clinical studies, patients who received baloxavir marboxil showed improvement in symptoms earlier than those receiving placebo. Baloxavir marboxil was well tolerated; rare side effects include diarrhea and bronchitis. Time to symptom improvement was not significantly different between baloxavir marboxil and oseltamivir, but baloxavir marboxil more rapidly decreases the influenza viral load compared with oseltamivir.

Ribavirin aerosol or oral tablets are used in the treatment of RSV infections in bone marrow transplant patients. Some studies suggest adjunctive immune globulin may reduce progression from upper to lower respiratory tract infection when used in combination with aerosolized ribavirin compared with aerosolized ribavirin used alone. **Nirsevimab** is a monoclonal antibody with activity against RSV reserved for neonates and infants up to 24 months at risk for severe RSV disease. Intravenous ribavirin (compassionate use availability only) can significantly lower the fatality rate of Lassa fever and has been used for hantavirus; however, the benefit is unclear. While used in some patients in the treatment of severe acute respiratory syndrome (SARS), its value and tolerability have been debated. The use of intravenous high-dose ribavirin has been associated with a high rate of anemia, hypomagnesemia, and bradycardia in the treatment of SARS. *The medication is teratogenic in animals, and pregnant persons should avoid contact with ribavirin.* As an alternative to the inhaled preparation, oral ribavirin is effective and well tolerated for the treatment of upper and lower RSV infections (with or without immune globulin) in immunocompromised patients.

Remdesivir, a nucleoside analog RNA polymerase inhibitor, is available for the treatment of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) in hospitalized patients and nonhospitalized patients with mild to moderate SARS-CoV-2 infection who are at high risk for progression to severe disease (see Chapter 37). In a multinational, randomized trial, hospitalized patients infected with SARS-CoV-2 who received remdesivir showed a significant reduction in the time to recovery compared with those who received placebo; those requiring supplemental oxygen benefited the most from remdesivir treatment. When studied in unvaccinated outpatients with mild to moderate SARS-CoV-2 infection, 3 days of remdesivir resulted in a significant reduction in hospitalization or death. Although these findings are favorable, the intravenous administration of remdesivir complicates its use in outpatient groups at high risk. Remdesivir is administered as a once-daily intravenous infusion dosed at 200 mg on the first day followed by 100 mg intravenously daily thereafter for a total of 5–10 days in inpatients and a total of 3 days in outpatients. Common adverse effects include transaminitis and nausea. A slower infusion of 120 minutes may mitigate the risk of hypersensitivity infusion reactions.

Nirmatrelvir in combination with **ritonavir** is an orally available antiviral combination that is effective in preventing hospitalization, death, or both in nonhospitalized patients at a high risk who are infected with SARS-CoV-2. Nirmatrelvir/ritonavir is the preferred treatment for this population due to high rates of efficacy and convenience associated with oral administration compared with intravenous remdesivir. Nirmatrelvir acts as an inhibitor of SARS-CoV-2 protease, while ritonavir boosts nirmatrelvir concentrations through CYP inhibition. Both medications are taken together twice daily for a 5-day course. For optimal outcomes, nirmatrelvir/ritonavir should be administered as soon as possible and no later than 5 days after symptom onset. Care must be taken to screen patients for drug-drug interactions since ritonavir is a strong CYP 3A and P-glycoprotein inhibitor that can increase the levels of many other drugs. Nirmatrelvir/ritonavir has also been associated with a "viral rebound" effect where patients who initially test negative for SARS-CoV-2 infection test positive again for SARS-CoV-2 or symptoms recur after experiencing an initial resolution. Since viral rebound also occurs in the absence of treatment and since episodes with nirmatrelvir/ritonavir occur infrequently (and, when they do, have primarily been associated with mild symptoms), this medication continues to be recommended.

Molnupiravir targets viral RNA polymerase, causing significant mutations in viral RNA and ultimately halting viral replication. Molnupiravir also shows favorable bioavailability as an oral SARS-CoV-2 therapeutic. Dosed at 800 mg orally twice daily for 5 days, molnupiravir is rapidly absorbed after oral administration and is well tolerated. Due to theoretical risk for human DNA mutagenesis and fetal malformations reported in animal studies, some have raised concern about using molnupiravir during pregnancy and lactation. Molnupiravir has demonstrated lower clinical efficacy relative to other antivirals (eg, nirmatrelvir/ritonavir) and is thus considered an alternative therapy for outpatients at high risk with mild to moderate SARS-CoV-2 infection who have no other treatment options. For a full review of remdesivir and other SARS-CoV-2 therapeutics, see Chapter 37.

AGENTS FOR HERPESVIRUSES & CYTOMEGALOVIRUS

Acyclovir is active against herpes simplex virus and varicella-zoster virus. In herpes-infected cells, it is selectively active against viral DNA polymerase and thus inhibits virus proliferation. Given intravenously (15 mg/kg/day in three divided doses), it is useful in the treatment of mucocutaneous herpes simplex in immunocompromised patients. It can reduce pain, accelerate healing, and prevent dissemination of herpes zoster and varicella in immunocompromised patients. The usual dosage for serious varicella-zoster infections is greater, ie, 30 mg/kg/day intravenously divided in three equal doses. The medication has no effect on establishment of latency or frequency of recurrence. *Oral acyclovir does* not *significantly reduce the incidence of postherpetic neuralgia*. Acyclovir (30 mg/kg/day intravenously in three equal doses) is the medication of choice for herpes encephalitis. Intravenous or oral acyclovir is effective prophylaxis against recurrent mucocutaneous and visceral herpes infections in transplant and other severely immunosuppressed patients. Prophylactic intravenous or oral acyclovir is effective in preventing cytomegalovirus (CMV) disease in some transplant settings (kidney and perhaps bone marrow) but not in others (liver).

Oral acyclovir, 400 mg three times daily for 7–10 days, is effective in primary genital herpes simplex infections. Oral acyclovir at a dose of 800 mg three times a day for 2 days for recurrent genital herpes reduces viral shedding and symptoms. Suppressive therapy (400 mg twice daily) for 4–6 months reduces the frequency and severity of recurrent genital herpetic lesions. Acyclovir minimally affects symptoms or viral shedding in recurrent herpes labialis and is not generally used for this disease. However, in a dose of 400 mg twice daily, it is effective in preventing recurrent herpes labialis in those with frequent relapses and in preventing sun-induced relapses.

Other uses of oral acyclovir include (1) acceleration of healing of herpes zoster in immunocompetent patients if initiated within 48 hours after onset (800 mg five times daily for 7 days), (2) more rapid healing of rash and lessened clinical symptoms of primary varicella in adults and children if instituted within 24 hours after onset of rash and continued for 5–7 days, (3) prevention of herpes simplex (in doses of 400–800 mg orally twice daily) and CMV infections in transplant recipients (in doses of 800 mg four or five times daily), and (4) prophylaxis against varicella in susceptible household contacts.

Oral acyclovir is significantly more efficacious than topical therapy in the treatment of herpes simplex mucocutaneous oral lesions in immunosuppressed patients.

The absolute oral bioavailability of acyclovir is 10–30%. Famciclovir and valacyclovir (see below) are significantly better absorbed than oral acyclovir and can be administered less frequently. Dosage reduction in kidney disease is required. Since hemodialysis reduces serum levels significantly, the daily dose should be given after hemodialysis.

Acyclovir is relatively nontoxic. Precipitation of medication in renal tubules has been described with intravenous acyclovir and can be avoided by maintaining adequate hydration and urine flow. Resistance has been described, usually in immunosuppressed patients who have received multiple courses of therapy.

Famciclovir is a prodrug of penciclovir. After oral administration, 75–80% is absorbed and deacetylated in the intestinal wall to the active drug, penciclovir. Penciclovir, like acyclovir, inhibits viral replication by interfering with viral DNA polymerase. Acyclovir-resistant strains of herpes simplex and varicella-zoster virus are also resistant to famciclovir. Famciclovir in a dose of 500 mg three times daily for 7 days accelerates healing of lesions in acute herpes zoster if started within 72 hours after the onset of rash. Famciclovir dosed at 250 mg three times daily for 7–10 days can be used for initial episodes of genital herpes and dosed 125 mg twice daily for 5 days for recurrent genital herpes. At a dose of 250 mg twice daily, it can be considered for chronic suppressive therapy, though its less effective than acyclovir or valacyclovir.

Valacyclovir is a prodrug of acyclovir that has significantly increased oral bioavailability when compared with acyclovir. After absorption, it is converted to acyclovir and serum levels are three to five times higher than those achieved with acyclovir. Valacyclovir at a dosage of 1 g three times daily for 7–10 days is effective therapy for herpes zoster when started within 72 hours after onset of rash and is slightly more effective than acyclovir in relieving zoster-associated pain. It shortens the course of initial episodes of genital herpes (1 g twice daily for 7–10 days), can be used to treat recurrent genital herpes (500 mg twice daily for 3 days), and is effective prophylaxis for recurrent genital herpes when given as a single 1-g daily dose. Valacyclovir prophylaxis (500 mg daily) reduces the rate of viral shedding and transmission of herpes in discordant monogamous couples, though it is thought to be less effective in people with frequent recurrences (> 10 episodes/year). At doses of 2 g four times daily, valacyclovir is more effective than placebo in preventing CMV infections in seronegative recipients of a kidney from a seropositive donor. The adverse effect profile of valacyclovir is comparable to that of acyclovir.

Ganciclovir is an analog of acyclovir with similar antiviral activity, including activity against CMV, that is administered by intravenous injection. **Valganciclovir** is an orally available prodrug of ganciclovir that achieves similar serum levels. Ganciclovir is frequently used in solid organ and stem cell transplant patients in the treatment and prevention of CMV infection. However, there is no uniformity of opinion about the duration of therapy or the route of administration. Before the availability of oral valganciclovir, anti-CMV therapy with intravenous ganciclovir frequently was administered in the immediate posttransplant period for 1–2 weeks, depending on the type of transplant and risk of developing CMV disease. Under current practice, patients at high risk are routinely screened for CMV DNA in blood by antigen detection or PCR. A positive test results in subsequent preemptive therapy with intravenous ganciclovir or oral valganciclovir.

The major adverse effect associated with valganciclovir and ganciclovir is neutropenia; this is reversible but may require the concomitant use of colony-stimulating factors. Thrombocytopenia, nausea, rash, and phlebitis occur less commonly.

Foscarnet (trisodium phosphonoformate) is a pyrophosphate analog that inhibits viral DNA polymerase of human herpesviruses (CMV, herpes simplex, varicella-zoster) and the reverse transcriptase of HIV. Compared to acyclovir and ganciclovir, foscarnet is poorly tolerated and more difficult to administer. Therefore, its use is limited to patients who do not respond to or cannot tolerate ganciclovir or acyclovir. Isolates of ganciclovir-resistant CMV and acyclovir-resistant herpes simplex and varicella-zoster usually are susceptible to foscarnet. Oral absorption is poor, and the medication must be given intravenously. The half-life is 3–5 hours, and this is prolonged with kidney disease. The usual induction dose is 60 mg/kg/dose every 8 hours, and the dose for maintenance therapy is 120 mg/kg once daily. Adjustments are required for even minimal impairment in kidney function.

Foscarnet can cause severe phlebitis; thus, central intravenous administration is generally used. Nephrotoxicity, which is dose-dependent and reversible, is the major toxicity. Prehydration with 2.5 L of 0.9% saline reduces nephrotoxicity. Foscarnet binds divalent cations, and hypocalcemia, peripheral neuropathy, seizures and arrhythmias, hypomagnesemia, and hypophosphatemia can occur. Monitoring of electrolytes and kidney function is required during therapy. Anemia (20–50%) and nausea and vomiting (20–30%) are other common adverse effects.

Cidofovir is a nucleotide analog that is active against almost all human herpesviruses and poxviruses via viral DNA synthesis inhibition. The medication has a prolonged pharmacokinetic intracellular half-life, allowing for administration every 1–2 weeks. Strains of CMV, herpes simplex virus, and herpes zoster virus that are resistant to ganciclovir or acyclovir often are susceptible to cidofovir. However, the least likely cross-resistance is between foscarnet and cidofovir. Cidofovir delays progression of CMV retinitis in newly diagnosed disease (5 mg/kg weekly for 2 weeks, followed by maintenance of 3–5 mg/kg every other week) and is effective therapy in relapsed disease or in patients who are intolerant of traditional therapy (5 mg/kg every other day). Cidofovir is associated with a high incidence of nephrotoxicity, sometimes severe. To avoid this complication, probenecid, an inhibitor of active tubular secretion, and intravenous saline must be administered with each dose. Ocular toxicity, including uveitis and iritis, is another complication reported with cidofovir.

Brincidofovir, a prodrug of cidofovir, is available as an oral preparation that causes less nephrotoxicity relative to cidofovir. Although only approved for the treatment of smallpox, brincidofovir retains activity against a wide variety of other viruses, such as nonvariola orthopoxvirus, CMV, adenovirus, and ebolavirus, among others. However, use of brincidofovir outside its labeled indication should be done with caution, particularly when used for longer durations, since brincidofovir has been associated with increased mortality (16%) relative to placebo (10%) when used for CMV prophylaxis. Aside from this consideration, the most adverse reactions are GI disorders (diarrhea, nausea, and vomiting).

Letermovir is a CMV DNA terminase complex inhibitor approved for CMV prophylaxis in allogeneic hematopoietic stem cell transplant recipients and kidney transplant recipients at a high risk. Compared with placebo, letermovir therapy results in significantly fewer CMV infections within 6 months of allogeneic hematopoietic stem cell transplantation. In kidney transplant recipients at a high risk, prophylactic letermovir was noninferior to valganciclovir for prevention of CMV disease and better tolerated with less neutropenia and leukopenia. Letermovir is administered as an intravenous infusion or oral tablet at 480 mg once daily. As an inhibitor of CYP3A, letermovir can increase concentrations of CYP3A substrates such as amiodarone, HMG-CoA reductase inhibitors, and immunosuppressants such as cyclosporine, tacrolimus, and sirolimus. Letermovir also induces CYP2C9 and 2C19 as well as inhibits hepatic organic anion transporters that are responsible for uptake of certain medications. Since letermovir is also a substrate of many drug enzymes, including CYP3A4, letermovir concentrations can be affected by CYP inducers/inhibitors (eg, cyclosporine, rifampin). A dose reduction from 480 mg to 240 mg once daily is recommended if cyclosporine is coadministered with letermovir. Patients receiving letermovir should be closely evaluated for drug interactions. The most common side effects of letermovir, compared with placebo, are vomiting, edema, and atrial fibrillation or flutter.

Maribavir, a benzimidazole riboside that inhibits CMV *UL97* kinase, is an orally available medication with activity against CMV and Epstein-Barr virus. Maribavir generally does not demonstrate cross-resistance with other CMV therapies due to its unique mechanism of action. However, development of maribavir resistance has been reported in patients receiving salvage therapy. Initial clinical trials found maribavir 100 mg twice daily did not prevent CMV disease; however, a subsequent trial that included hematopoietic stem-cell and solid organ transplant recipients with CMV infection found that patients who received maribavir 400 mg orally twice daily had a significant increase in CMV clearance compared to standard therapy with similar all-cause mortality. Maribavir was also better tolerated; the most common adverse effects are anemia, diarrhea, nausea, vomiting, dysgeusia, and fatigue.

HEPATITIS B AGENTS

For a full review of chronic hepatitis B diagnosis and management, see Chapter 18.

The antiretroviral **tenofovir disoproxil fumarate**, dosed 300 mg orally daily, is particularly useful in the treatment of hepatitis B virus (HBV) in patients who have HIV and hepatitis B coinfection. The primary toxicity associated with tenofovir is nephrotoxicity. Other adverse effects include osteomalacia and lactic acidosis. **Tenofovir alafenamide**, an alternative formulation of tenofovir dosed at 25 mg orally daily, is noninferior to tenofovir disoproxil fumarate for the treatment of chronic hepatitis B infection with favorable effects on bone mineral density and kidney function. However, tenofovir alafenamide can cause dyslipidemia and weight gain and is also associated with lactic acidosis.

Entecavir is a nucleoside analog medication that has selective anti-HBV activity. For patients with chronic hepatitis B who are beginning treatment for the first time (nucleoside-naïve patients), the recommended dosage of entecavir is a single 0.5-mg tablet taken once daily on an empty stomach; for those patients infected with lamivudine-resistant isolates or with decompensated cirrhosis, a single 1-mg tablet is taken once daily. While entecavir is useful for lamivudine-resistant isolates, cross-resistance has been observed among HBV nucleoside analogs. In cell-based assays, entecavir was associated with an 8- to 30-fold less inhibition of replication of HBV that contained lamivudine-resistant mutations than of wild-type virus. Adverse events are similar to those of other hepatitis B agents and include severe, acute exacerbation of hepatitis B after discontinuation as well as headache, abdominal pain, diarrhea, fatigue, and dizziness.

Second line options for management of HBV include **lamivudine, adefovir, and telbivudine**. **Lamivudine** (3TC), a well-tolerated oral antiviral nucleoside analog used in treatment of HIV infection, is dosed at 100 mg once-daily, While lamivudine is useful, development of resistance is common with long-term therapy. Therapy after liver transplantation is associated with a reduced risk of reinfection with hepatitis B.

Adefovir is an antiviral agent with activity against hepatitis B. It is as effective against lamivudine-susceptible and lamivudine-resistant isolates. While previously used higher doses have been associated with substantial nephrotoxicity, this complication is rare with the lower doses (10 mg/day) used to treat hepatitis B.

Telbivudine, dosed 600 mg orally daily, is also active against both lamivudine-susceptible and lamivudine-resistant isolates and comparative trials demonstrate clear superiority over lamivudine. The advantages over lamivudine include both viral suppression as well as normalization of ALT. It is well absorbed by the oral route, and food has no impact upon bioavailability. The adverse effect profile is comparable with that observed with other nucleoside analogs. Telbivudine is no longer available in the United States but still used in some countries.

HEPATITIS C AGENTS

For a full review of chronic hepatitis C diagnosis and management, see Chapter 18.

Human interferons have been prepared from stimulated lymphocytes and by DNA recombinant technology. These agents have antiviral, antitumor, and immunoregulatory properties. The most common uses of these agents include therapy of chronic hepatitis due to hepatitis B, C, and D (see Chapter 18). Adverse effects are common and include influenza-like illness with fever, chills, nausea, vomiting, headache, arthralgias, and myalgias. Bone marrow suppression, especially with high-dose interferon therapy, also occurs. Considering the poor tolerability of interferon and excellent efficacy of direct-acting antiviral agents, few patients any longer are candidates for interferon-based combination therapy.

An extensive list of effective HCV treatments exists, including direct-acting antiviral agents and host-targeting antiviral agents. These agents all differ in terms of efficacy, breadth of genotypic coverage, probability of drug resistance, and side effects. Many antivirals used for the treatment of HCV are cytochrome P450 substrates that interact with other drugs, and patients taking these medications should be monitored closely for drug interactions. Regimens for HCV infection typically include a NS5A inhibitor (eg, **elbasvir, ledipasvir, pibrentasvir, velpatasvir, daclatasvir)** in combination with either a NS5B RNA polymerase inhibitor (eg, **sofosbuvir**) or NS3/4 protease inhibitor (eg, paritaprevir, simeprevir, voxilaprevir, **grazoprevir, glecaprevir**).

Glecaprevir/pibrentasvir and **sofosbuvir/velpatasvir** are recommended as first-line therapy for all genotypes (1–6) in treatment-naïve adults with or without compensated cirrhosis. Glecaprevir/pibrentasvir allows for a shorter treatment duration of 8 weeks (compared with 12 weeks) for treatment-naïve patients living with HCV who are noncirrhotic or have compensated cirrhosis. Glecaprevir/pibrentasvir can be administered in patients with kidney impairment, including ESKD, without dose adjustment. However, glecaprevir/pibrentasvir has a high pill burden with three tablets taken together once daily. Sofosbuvir/velpatasvir is a fixed-dose combination product administered as one pill once daily for 12 weeks regardless of cirrhosis status. For patients coinfected with HIV, sofosbuvir/velpatasvir does not interact with HIV protease inhibitors but cannot be used with efavirenz, etravirine, or nevirapine, since these medications decrease the levels of velpatasvir.

In patients with decompensated cirrhosis, **ledipasvir/sofosbuvir** (genotypes 1, 4, 5, or 6) or **sofosbuvir/velpatasvir** (genotypes 1–6) are recommended in combination with ribavirin for 12 weeks, if eligible, or for 24 weeks without ribavirin. Ledipasvir/sofosbuvir can be safely coadministered with most antiretrovirals; however, patients on tenofovir-based regimens should have an eGFR of at least 60 mL/min/1.73 m^2 while taking either ledipasvir/sofosbuvir or sofosbuvir/velpatasvir.

Sofosbuvir in combination with velpatasvir and voxilaprevir is a combination product approved for patients with prior treatment failure with a NS5A inhibitor-based regimen for any genotype or genotypes 1a or 3 infection who have failed a sofosbuvir-containing regimen. Those with genotype 3 and prior failed sofosbuvir-containing regimen should have ribavirin added to sofosbuvir/velpatasvir/voxilaprevir.

All direct-acting HCV antiviral medications must include a boxed warning regarding the risk of HBV reactivation. Patients should be screened for current or past HBV infection before starting treatment with a direct-acting HCV antiviral and monitored for HBV reactivation during and following treatment (see Chapter 18).

Part e2: Diagnostic Testing & Medical Decision-Making

Overview: Diagnostic Testing & Medical Decision-Making

e2-01

Chuanyi Mark Lu

The clinician's main task is to make reasoned decisions about patient care based on available clinical information and estimated clinical outcomes. Although data obtained from the history and physical examination may be sufficient for making a diagnosis or for guiding therapy, more information is often required. Today's clinicians rely increasingly on diagnostic tests and face challenges in selecting which tests to order and in interpreting test results. This chapter aims to help clinicians understand the utility as well as the limitations of diagnostic testing in clinical diagnosis and management.

e2-02

Benefits, Risks, & Costs of Diagnostic Tests

Chuanyi Mark Lu

When used appropriately, diagnostic tests can be of great assistance to the clinician. Tests can be used for **screening,** to identify risk factors for disease and to detect occult disease in asymptomatic persons. Identification of risk factors may allow early intervention to prevent disease occurrence, and early detection of occult disease may reduce disease morbidity and mortality through early treatment. Blood pressure measurement is recommended for preventive care of asymptomatic low-risk adults. Screening for breast, cervix, and colon cancer is also recommended, whereas screening remains controversial for prostate cancer (using PSA), lung cancer in patients without a history of smoking or other risk factors (using low-dose CT), and thyroid cancer. Screening without demonstrated benefits should be avoided. Optimal screening tests should meet the criteria listed in Table e2–1. Some positive screening test results (eg, rapid HIV antibody [Ab] tests) require confirmatory testing.

Table e2–1. Criteria for use of screening procedures.

Characteristics of population
1. Sufficiently high prevalence of disease.
2. Likely to be compliant with subsequent tests and treatments.
Characteristics of disease
1. Significant morbidity and mortality.
2. Effective and acceptable treatment available.
3. Presymptomatic period detectable.
4. Improved outcome from early treatment.
Characteristics of test
1. High sensitivity and specificity.
2. Cost-effective and low-risk.
3. Confirmatory test available and practical.

Reproduced with permission from Nicoll D et al. *Guide to Diagnostic Tests,* 7th ed. McGraw-Hill, 2017.

Tests can be used for **diagnosis,** ie, to help establish or exclude the presence of disease in symptomatic persons. Some tests assist in early diagnosis after onset of symptoms and signs; others assist in developing a differential diagnosis; others help determine the severity, activity, or stage of disease.

Tests can also be used in **patient management.** They can help (1) estimate prognosis and facilitate treatment decision-making; (2) monitor the course of disease to determine whether it is stable, is refractory, is progressive, has recurred, or is in remission; (3) select drugs and adjust therapy; and (4) determine necessity of hospital admission and readiness for discharge.

One evolving field of medicine is **personalized medicine,** which involves tailoring treatment to the individual patient. **Precision medicine** is emerging as a tool to match patients with the appropriate treatment based on the precise biologic and molecular characteristics of an individual patient's disease (cancer, in particular). As an example, only patients with breast cancer that shows overexpression of HER2 protein or extra copies of the *HER2* gene or both could benefit from trastuzumab treatment. The associated **companion diagnostics** for the safe and effective use of various drugs is rapidly evolving.

When ordering diagnostic tests, clinicians should weigh the potential benefits against the potential costs and adverse effects (ie, test stewardship). Some tests carry a risk of morbidity or mortality—eg, cerebral angiogram leads to stroke in 0.5% of cases. The potential discomfort associated with tests such as colonoscopy may deter some patients from completing a diagnostic workup. The result of a diagnostic test may mandate additional testing or frequent follow-up, and the patient may incur significant cost, risk, and discomfort during follow-up procedures.

Furthermore, a false-positive test may lead to incorrect diagnosis, further unnecessary testing, or unnecessary treatment. Classifying a healthy patient as having a disease based on a falsely positive diagnostic test can cause psychological distress and may lead to risks from unnecessary or

---

inappropriate therapy. A screening test may identify disease that would not otherwise have been recognized and that would not have affected the patient. For example, early-stage prostate cancer detected by PSA screening in a 76-year-old man with known HF will probably not become symptomatic during his lifetime, and aggressive treatment may result in net harm. Similarly, routine preoperative testing should be discouraged, ie, preoperative testing needs to be considered carefully based on a targeted history, physical examination findings, and type of surgery.

The costs of diagnostic testing must also be understood and considered. Total costs may be high, patient out-of-pocket costs may be prohibitive, or **cost-effectiveness** may be unfavorable. Even relatively inexpensive tests may have poor cost-effectiveness if they produce very small health benefits. Factors adversely affecting cost-effectiveness include ordering a panel of tests when one test would suffice or option of reflex testing is available, ordering a test more frequently than necessary, ordering an inappropriate or incorrect test, ordering a duplicative test, and ordering a test for medical record documentation only. The value-based, operative question for test ordering is, “Will the test result help establish a diagnosis, affect a treatment decision, or help predict a prognosis?” If the answer is “no,” then the test is not justified. Unnecessary tests generate unnecessary labor, reagent, and equipment costs, and lead to high health care expenditures. Optimizing test utilization helps health care systems reduce costs, decrease waste, and improve patient care.

Molecular and genetic testing is readily available, and next-generation DNA and RNA sequencing technologies and cell-free DNA “liquid biopsy” for cancer testing are increasingly applied in the clinical diagnostic realm. Many are “laboratory developed tests” (developed, manufactured, and used within a single academic or commercial laboratory), and their cost-effectiveness and health outcome benefits need to be carefully examined. Genetic testing can yield indeterminate results (eg, variants of unknown significance) that may lead to medical dilemmas for both provider and patient. Determining when and how to incorporate genetic and molecular testing into practice in a cost-effective manner is often complicated but critical. Diagnostic genetic testing based on symptoms (eg, testing for fragile X in a boy with intellectual disabilities) differs from predictive genetic testing (eg, evaluating a healthy person with a family history of Huntington disease) and from disease predisposition genetic testing, which may indicate relative susceptibility to certain hereditary conditions or response to certain drug treatment (eg, *BRCA1/BRCA2* or *HER2* testing for breast cancer). The outcome benefits of many newly available pharmacogenetic tests have not yet been established by prospective clinical studies; eg, there is insufficient evidence that genotypic testing for warfarin dosing leads to outcomes that are superior to those using conventional dosing algorithms, in terms of reduction of out-of-range INRs. Other testing (eg, testing for inherited causes of thrombophilia, such as factor V Leiden, prothrombin gene variants, etc) has only limited value for managing patients, since knowing whether a patient has inherited thrombophilia generally does not change the intensity or duration of anticoagulation treatment. Hereditary disease testing (eg, hereditary cancer screen), carrier testing (eg, for cystic fibrosis), and prenatal fetal testing (eg, for Down syndrome) often require **genetic counseling** of patients so that there is adequate understanding of the clinical, social, ethical, and sometimes legal impact of the results.

Clinicians order and interpret large numbers of laboratory tests every day, and the complexity of these tests continues to increase. The large and growing test menu and the inconsistencies in nomenclature for many tests have introduced significant challenges for clinicians, ie, selecting the correct laboratory test and correctly interpreting the test results. Errors in test selection and test results interpretation are common and could impact patient safety but are often difficult to detect. Using evidence-based testing algorithms that provide guidance for test selection in specific disorders and expert-driven test interpretation (eg, reports and interpretative comments generated by clinical pathologists) can help decrease such errors. Consultation and collaboration with laboratory professionals (ie, pathologists, clinical laboratory scientists) can help improve the timeliness of diagnostic testing and optimize laboratory test utilization.

e2-03

Diagnostic Test Preparation

Chuanyi Mark Lu

Factors affecting both the patient and the specimen are important in test preparation. The most crucial element in a properly conducted laboratory test is an appropriate specimen.

PATIENT PREPARATION

Preparation of the patient is important for certain tests—eg, a fasting state is needed for optimal glucose and lactose tolerance tests; posture and sodium intake should be strictly controlled when measuring renin and aldosterone levels; and strenuous exercise should be avoided before taking samples for creatine kinase determinations, since vigorous muscle activity can lead to falsely abnormal results. For certain tests, supplements should be avoided before testing (eg, biotin supplements should be avoided for 24–36 hours before thyroid function testing). Patients should rest for 15 minutes or more, either lying or sitting before blood specimen collection.

SPECIMEN COLLECTION

Careful attention must be paid to patient identification and specimen labeling—eg, two patient identifiers (name and birth date, or name and unique institutional identifier) must be used. Documenting when the specimen was collected is important. Correct timing is also important, particularly in therapeutic drug monitoring. For instance, aminoglycoside levels cannot be interpreted appropriately without knowing whether the specimen was drawn just before (“trough” level) or after (“peak” level) drug administration. Drug levels cannot be interpreted if they are drawn during the drug’s distribution phase (eg, digoxin levels drawn during the first 6 hours after an oral dose). Another example is monitoring of unfractionated heparin (UFH) infusion, ie, specimen should be collected 6 hours after initiation of UFH infusion and 6 hours after any change in UFH infusion rate. Substances that have a circadian variation (eg, cortisol) can be interpreted only in the context of the time of day the sample was drawn. Testing for glucose-6-phosphate dehydrogenase (G6PD) deficiency is usually performed 2–3 months after a hemolytic episode, since G6PD enzyme activity may be spuriously normal shortly after acute hemolysis.

During specimen collection, certain principles and standard operative procedures must be followed. Standard blood collection devices and appropriate vacuum tubes (ie, those containing appropriate anticoagulant or gel separator or both for serum or plasma preparation) should be used. Specimens should not be drawn above an intravenous line or from an indwelling line because this may contaminate the sample with intravenous fluid and drug (eg, heparin). Excessive tourniquet time leads to hemoconcentration and an increased concentration of protein-bound substances such as calcium. Hemolyzed specimen can be a problem because lysis of cells during blood sample collection results in spuriously increased serum levels of substances that are normally concentrated in cells (eg, LD and potassium). Certain test specimens may require special handling, transport, processing, or storage conditions (eg, specimens for blood gas, serum cryoglobulin, and nucleic acid-based molecular tests). Delay in delivery of specimens to the laboratory can result in ongoing cellular metabolism and therefore spurious results for some studies (eg, low serum glucose). Correct collection, handling, and storage of nasopharyngeal swab or saliva specimens are critical for detecting virions and antigens (eg, SARS-CoV-2, which causes COVID-19). All specimens must be labeled according to established policy and procedure to avoid misidentification.

Preanalytical errors have been reported to account for 75% of testing errors, which is a potential patient safety issue and can be costly. Collaboration between laboratory personnel and health care providers is crucial to ensure the reliability of diagnostic tests.

There is growing interest in point-of-care testing, for which specimen collection and handling are equally important. Point-of-care testing involves extensive quality assurance as well as training and periodic competency evaluation of those at the site of care delivery (eg, staff in operating room, emergency department, ICU, and outpatient clinics). The unit cost per test is high, through loss of economy of scale offered by automation in main laboratory, but there are potential benefits to patient care

because of rapid delivery of results and potential reduction of other facility costs.

e2-04

Diagnostic Test Characteristics

Chuanyi Mark Lu

Table e2–2 lists the general characteristics of useful diagnostic tests. Most of the principles detailed below can be applied not only to laboratory and radiologic tests, but also to elements of the history and physical examination. An understanding of these characteristics is helpful to the clinician when ordering and interpreting diagnostic tests.

ACCURACY

The accuracy of a laboratory test is its correspondence with or closeness to the true value. A test is deemed inaccurate when the result differs from the true value even though the results may be reproducible (Figure e2–1A); this is also called systematic error (or bias). For example, serum creatinine is commonly measured by a kinetic Jaffe method, which has a systematic error as large as 0.23 mg/dL (20.33 mcmol/L) when compared with the gold standard gas chromatography–isotope dilution mass spectrometry method. In the clinical laboratory, accuracy of tests is maximized by calibrating laboratory equipment with standard reference material (ie, calibrator) and evaluated by participation in external proficiency testing programs (eg, proficiency testing program offered by the College of American Pathologists).

Table e2–2. Properties of useful diagnostic tests.

1. Test methodology has been described in detail so that it can be accurately and reliably reproduced.
2. Test accuracy, precision, and reportable range have been determined.
3. The reference interval(s) have been established appropriately.
4. Clinical sensitivity and specificity have been reliably established by comparison with a gold standard. The evaluation has used a range of patients, including those who have different but commonly confused disorders and those with a spectrum of mild and severe, treated and untreated disease. The patient selection process has been adequately described so that results will not be generalized inappropriately.
5. Independent contribution to overall performance of a test panel has been confirmed if a test is advocated as part of a panel of tests.
6. Test is accessible and affordable.

Reproduced with permission from Nicoll D et al. *Guide to Diagnostic Tests,* 7th ed. McGraw-Hill, 2017.

PRECISION

Test precision is a measure of a test's reproducibility or repeatability when repeated on the same sample. If the same specimen is analyzed many times, some variation in results (random error) is expected; this variability is expressed as a coefficient of variation (CV: the standard deviation [SD] divided by the mean, often expressed as a percentage, ie, CV% = [SD/Mean] × 100). For example, when the laboratory reports a CV of 5% for serum creatinine and accepts results within ± 2 standard deviations, it denotes that, for a sample with serum creatinine of 1.0 mg/dL (88.4 mcmol/L), the laboratory may report the result as anywhere from 0.90 mg/dL (79.56 mcmol/L) to 1.10 mg/dL (97.24 mcmol/L) on repeated measurements from the same sample.

An imprecise test is one that yields widely varying results on repeated measurements (Figure e2–1B). The precision of diagnostic tests, which is monitored in clinical laboratories by using quality control material, must be good enough to distinguish clinically relevant changes in a patient's status from the analytic variability (imprecision) of the test. For instance, the manual peripheral blood WBC differential count may not be precise enough to detect important changes in the distribution of cell types seen in blood, because it is calculated by subjective evaluation of a small sample (eg, 100–200 cells). Repeated measurements by different technologists on the same sample result in widely differing results. Automated white cell differential counts are more precise because they are obtained from machines that use objective physical characteristics to classify a larger sample (eg, 10,000 cells or greater).

The lower and upper limits of a quantitative test are dependent on the test precision. As an example, the lower report limit (known as limit of quantitation) of

---

Source: Chapter adapted and updated, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.

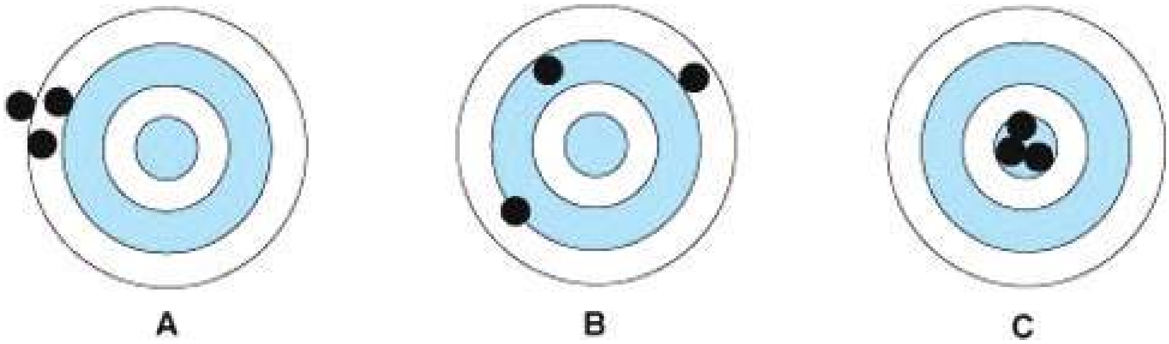

Figure e2–1. **Relationship between accuracy and precision in diagnostic tests. The center of the target represents the true value of the substance being tested. A: A diagnostic test that is precise but inaccurate; repeated measurements yield very similar results, but all results are far from the true value. B: A test that is imprecise and inaccurate; repeated measurements yield widely different results, and the results are far from the true value. C: An ideal test that is both precise and accurate.** (Reproduced, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.)

high-sensitivity troponin I (TnI) test is 2–3 ng/L (versus 30–40 ng/L for conventional TnI test) because high-sensitivity test has higher precision at very low TnI levels.

A diagnostic laboratory can estimate the total analytic error (TAE) for a quantitative test based on its accuracy (bias) and precision (SD) as TAE = (Bias + 2 SD) [or TAE = (Bias + 1.65 SD) for a one-sided estimate]. A test's TAE must be within specified tolerance limits, such as those defined by the Clinical Laboratory Improvement Amendments.

An accurate and precise measurement are the primary characteristics of the ideal, valid test (Figure e2–1C).

SIGMA METRICS

The Sigma metric is used to measure the overall quality of a laboratory test. It is a single numeric value that is calculated based on three traditional elements used to evaluate test performance: accuracy (bias), precision (CV), and allowable total error (ATE) (or tolerance limit of a test); the Sigma metric = (ATE – Bias)/CV (with all values expressed as percentage). On a scale of 0 to 6, a higher Sigma metric value means fewer analytical errors, ie, fewer questionable test results are accepted and reported, and fewer acceptable test results are falsely rejected and not reported. A Sigma metric of 6 for a test indicates that it can be considered "world class," meaning > 99% of test results are error-free. On the other hand, a test with a Sigma metric of 3 or less is generally considered unreliable and should not be used.

REFERENCE INTERVAL

Some diagnostic tests are reported as positive or negative, but most are reported quantitatively. Use of reference intervals is a technique for interpreting quantitative results. A reference interval is defined as the interval between and including the low and high reference limits, which are established from a reference population. Reference intervals are often method- and laboratory-specific. In practice, they often represent test results found in 95% of a small population presumed to be healthy; by definition, then, 5% of healthy patients will have an abnormal test result (Figure e2–2). Slightly abnormal results should be interpreted with caution—they may be either truly abnormal or falsely abnormal. Statistically, the probability that a healthy person will have two separate test results within the reference interval is 0.95 × 0.95 = 0.9025, or 90.25%; for five separate tests, it is 77.4%; for 10 tests, 59.9%; and for 20 tests, 35.8%. The larger the number of tests ordered, the greater the probability that one or more of the test results will fall outside the reference interval (Table e2–3). Conversely, values within the reference interval may not rule out the actual presence of disease since the reference interval does not establish the distribution of results in patients with disease. As such, reference intervals must be used within the context of medical knowledge about the disorder in question.

It is important to consider also whether published reference intervals are appropriate for the particular patient being evaluated, since some intervals depend on age, sex, affirmed gender, physiologic conditions (eg, pregnancy), weight, diet, time of day and sample collection, activity status, posture, or even season. Biologic variability occurs among individuals as well as within the same individual. For instance, serum estrogen levels in women vary from day to day depending on the menstrual cycle; serum cortisol shows diurnal variation, being highest in the morning and decreasing later in the day; and vitamin D shows seasonal variation with lower values in winter.

Table e5–3 of the Appendix contains the reference intervals for commonly used chemistry and hematology tests. Test performance characteristics such as sensitivity and specificity are needed to interpret results and are discussed below.

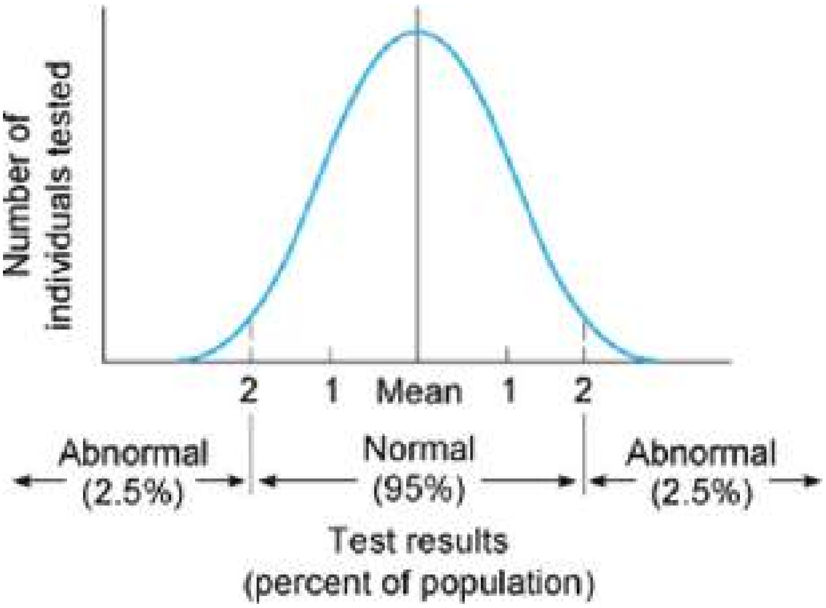

Figure e2–2. The reference interval is usually defined as within 2 SD of the mean test result (shown as −2 and 2) in a small population of healthy volunteers. Note that in this example, test results are normally distributed; however, many biologic substances have distributions that are skewed. (Reproduced, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.)

INTERFERING FACTORS

The results of diagnostic tests can be altered by external factors, such as ingestion of drugs and use of contrast media, and internal factors, such as abnormal physiologic states or drug-laboratory test interaction. These factors contribute to the biologic variability and must be considered in the interpretation of test results.

External interferences can affect test results in vivo or in vitro. In vivo, alcohol increases γ-glutamyl transpeptidase, and diuretics can affect sodium and potassium concentrations. Cigarette smoking can induce hepatic enzymes and thus reduce levels of substances such as theophylline that are metabolized by the liver. In vitro, cephalosporins may produce spurious serum creatinine levels due to interference with a common laboratory method of analysis. Biotin interferes with immunoassays using the biotin-streptavidin capture method and causes spurious tests results (eg, falsely low TSH and falsely elevated free T_4 and total T_3 levels). Therapeutic monoclonal antibodies (eg, daratumumab) can interfere with blood bank testing (eg, antibody screening and crossmatch tests) and impact the interpretation of serum protein electrophoresis. Eltrombopag, a thrombopoietin receptor agonist, causes discoloration of serum (could be misinterpreted as hemolysis) and also interferes with certain bilirubin Diazo assays. DOACs (eg, dabigatran, rivaroxaban, apixaban) affect most coagulation tests to variable degrees. PPIs cause elevation of chromogranin level (a marker for neuroendocrine tumor). Patients on continuous ambulatory peritoneal dialysis may have erroneously high blood glucose level due to presence of other sugars (eg, icodextrin or maltose) in dialysis fluid. Knowledge of drug-laboratory test interactions can help avoid misinterpretation of test results.

Table e2–3. Relationship between the number of tests and the probability that a healthy person will have one or more abnormal results.

Number of Tests	Probability That One or More Results Will Be Abnormal
1	5%
6	26%
12	46%
20	64%

Reproduced with permission from Nicoll D et al. *Guide to Diagnostic Tests,* 7th ed. McGraw-Hill, 2017.

Internal interferences result from abnormal physiologic states interfering with the test measurement. For example, patients with gross lipemia may have spuriously low serum sodium levels if the test methodology includes a step in which serum is diluted before sodium is measured, and patients with endogenous antibodies (eg, human anti-mouse antibodies, rheumatoid factor) may have falsely high or low results in automated immunoassays for various analytes.

Because of the potential for test interference, clinicians should be wary of unexpected test results and should investigate reasons other than disease that may explain abnormal results, including preanalytical and analytical laboratory errors.

SENSITIVITY & SPECIFICITY

Clinicians should use measures of test performance such as clinical sensitivity and specificity to judge the quality of a diagnostic test for a particular disease.

Test **sensitivity** is the ability of a test to detect disease and is expressed as the percentage of patients with disease in whom the test is positive. Thus, a test that is 90% sensitive gives positive results in 90% of patients with disease and negative results in 10% of patients with disease (false negatives). Generally, a test with high sensitivity is useful to exclude a diagnosis because a highly sensitive test renders few results that are falsely negative. To exclude infection with the virus that causes AIDS, for instance, a clinician might choose a highly sensitive test, such as the HIV p24 antigen and HIV-1/2 antigen/antibody combination fourth-generation rapid test (HIV-1/2 Ag/Ab Combo rapid test).

A test's **specificity** is the ability to detect absence of disease and is expressed as the percentage of patients without disease in whom the test is negative. Thus, a test that is 90% specific gives negative results in 90% of patients without disease and positive results in 10% of patients without disease (false positives). A test with high specificity is useful to confirm a diagnosis, because a highly specific test has few results that are falsely positive. For instance, to make the diagnosis of gouty arthritis, a clinician might choose a highly specific test, such as the presence of negatively birefringent needle-shaped urate crystals on microscopic evaluation of joint fluid or tissue sample.

Table e2–4 illustrates the generic structure of a 2 × 2 table (disease versus test) and the calculation formulas for test performance metrics including sensitivity, specificity, positive predictive value, and negative predictive value. To determine test sensitivity and specificity for a particular disease, the test must be compared against an independent "gold standard" test or established standard diagnostic criteria that define the true disease state of the patient. For instance, the sensitivity and specificity of rapid antigen detection testing in diagnosing group A β-hemolytic streptococcal pharyngitis are obtained by comparing the results of rapid antigen testing with the gold standard test, throat swab culture. Application of the gold standard test (ie, swab culture) to patients with positive and negative rapid antigen testing establishes sensitivity and specificity of the rapid test. However, for many disease states (eg, pancreatitis, vitamin B_{12} deficiency), an independent gold standard test either does not exist or is difficult or expensive to apply—and in such cases, reliable estimates of test sensitivity and specificity are sometimes difficult to obtain.

Sensitivity and specificity can also be affected by the population from which these values are derived. For instance, many diagnostic tests are evaluated first using patients who have severe disease and control groups who are young and well. Compared with the general population, this study group will have more results that are truly positive (because patients have more advanced disease) and more results that are truly negative (because the control group is healthy). Thus, test sensitivity and specificity will be higher than would be expected in the general population, where more of a spectrum of health and disease is found. Clinicians should be aware of this **spectrum bias** when generalizing published test results to their own practice. To minimize spectrum bias, the control group should include individuals who have diseases related to the disease in question, but who lack this principal disease. For example, to establish the sensitivity and specificity of the anti-cyclic citrullinated peptide test for rheumatoid arthritis, the control group should include patients with rheumatic diseases other than rheumatoid arthritis. Other biases, including spectrum composition, population recruitment, absent or inappropriate reference standard, and verification bias, should also be considered in certain situations, where critical appraisal of published articles may be necessary.

It is important to remember that the reported sensitivity and specificity of a test depend on the analyte level (threshold) used to distinguish a normal from an abnormal

Table e2–4. The 2 × 2 table (disease versus test) and test performance metric calculation formulas.

	Disease Present	Disease Absent	Total
Test Positive	TP (true positive)	FP (false positive)	(TP + FP)
Test Negative	FN (false negative)	TN (true negative)	(FN + TN)
Total	(TP + FN)	(FP + TN)	N = (TP + FP + FN + TN)

Sensitivity = (TP) ÷ (TP + FN)
Specificity = (TN) ÷ (TN + FP)
Positive Predictive Value(PPV) = (TP) ÷ (TP + FP)
Negative Predictive Value(NPV) = (TN) ÷ (TN + FN)

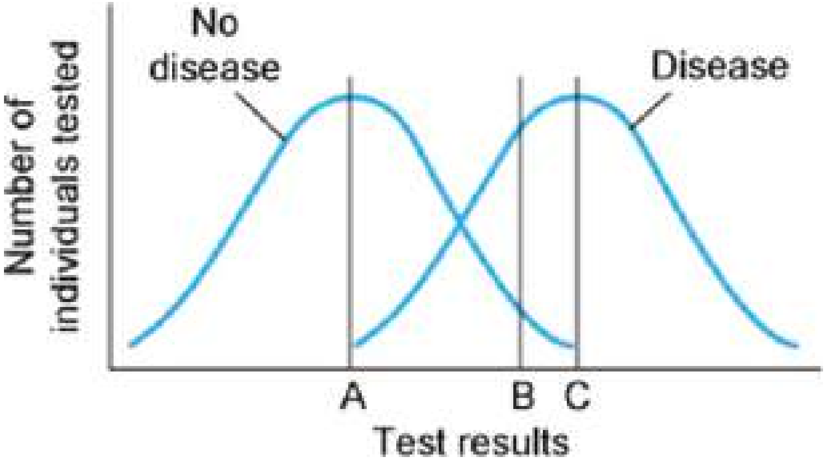

Figure e2–3. Hypothetical distribution of test results for healthy and diseased individuals. The position of the "cutoff point" between "normal" and "abnormal" (or "negative" and "positive") test results determines the test's sensitivity and specificity. If point A is the cutoff point, the test would have 100% sensitivity but low specificity. If point C is the cutoff point, the test would have 100% specificity but low sensitivity. For many tests, the cutoff point is determined by the reference interval, ie, the range of test results that is within 2 SD of the mean of test results for healthy individuals (point B). In some situations, the cutoff is altered to enhance either sensitivity or specificity. (Reproduced, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.)

test result. If the threshold is lowered, sensitivity is increased at the expense of decreased specificity. If the threshold is raised, sensitivity is decreased while specificity is increased (Figure e2–3).

Figure e2–4 and Table e2–4 show how test sensitivity and specificity can be calculated using test results from patients previously classified by the gold standard test as having disease or not having disease.

Receiver Operator Characteristic

The performance of two different tests can be compared by plotting the **receiver operator characteristic (ROC)** curves, which graphically represent the pairs of sensitivity and specificity at various reference interval cutoff values. Each point on the ROC curve represents a sensitivity/(1–specificity) pair corresponding to a particular decision threshold. The resulting curve for each test, obtained by plotting the sensitivity against (1–specificity), often shows which test is more accurate; a clearly superior test will have an ROC curve that always lies above and to the left of the inferior test curve, and, in general, the better test will have a larger area under the curve (AUC). For instance, Figure e2–5 shows the ROC curves for PSA and prostatic acid phosphatase in the diagnosis of prostate cancer. PSA is a superior test because it has significantly larger area under the curve and higher sensitivity and specificity for all cutoff values.

Note that, for a given test, the ROC curve also allows one to identify the cutoff value that minimizes both false-positive and false-negative results, which is located at the point closest to the upper-left corner of the curve. The optimal clinical cutoff value, however, depends on the condition being detected and the relative importance of false-positive versus false-negative results.

Use of Tests in Diagnosis & Management

Chuanyi Mark Lu

The usefulness of a test in a particular clinical situation depends not only on the test's characteristics (eg, sensitivity and specificity, which are not predictive measures) but also on the probability that the patient has the disease before the test result is known (pretest probability). Before ordering a diagnostic test in clinical practice, theoretical considerations on positive and negative predictive values need to be considered. The results of a useful test substantially change the probability that the patient has the disease (posttest probability). Figure e2–4 shows how posttest probability can be calculated from the known sensitivity and specificity of the test and the estimated pretest probability of disease (or disease prevalence), based on Bayes theorem.

The estimated pretest probability of disease, based on prevalence data, informed opinion, or consensus guidelines (eg, disease prediction score systems), has a profound effect on the posttest probability of disease. As demonstrated in Table e2–5, when a test with 90% sensitivity and specificity is used, the posttest probability can vary from 8% to 99% depending on the pretest probability of disease. Furthermore, as the pretest probability of disease decreases, it becomes more likely that a positive test result represents a false-positive.

Table e2–5. Influence of pretest probability on the posttest probability of disease when a test with 90% sensitivity and 90% specificity is used.

Pretest Probability	Posttest Probability
0.01	0.08
0.50	0.90
0.99	0.999

As an example, suppose the clinician wishes to calculate the posttest probability of prostate cancer using the PSA test and a cutoff value of 4 ng/mL (4 mcg/L). Using the data shown in Figure e2–5, sensitivity is 90% and specificity is 60%. The clinician estimates the pretest probability of disease given all the evidence and then calculates the posttest probability using the approach shown in Figure e2–4. The pretest probability that an otherwise healthy 50-year-old man has prostate cancer is equal to the prevalence of prostate cancer in that age group (probability = 10%), and the posttest probability after a positive test is only 20%. Even though the test is positive, there is still an 80% chance that the patient does not have prostate cancer (Figure e2–6A). If the clinician finds a prostate nodule on rectal examination, the pretest probability of prostate cancer rises to 50% and the posttest probability using the same test is 69% (Figure e2–6B). Finally, if the clinician estimates the pretest probability to be 98% based on a prostate nodule, bone pain, and lytic lesions on spine radiographs, the posttest probability using PSA is 99% (Figure e2–6C). This example illustrates that pretest probability has a profound effect on posttest probability and that tests provide more information when the diagnosis is truly uncertain (pretest probability about 50%) than when the diagnosis is either unlikely (eg, pretest probability is < 5%) or nearly certain (eg, pretest probability is > 95%).

e2-06

Likelihood Ratios & Odds-Probability Conversion in Medical Decision-Making

Chuanyi Mark Lu

A practical way to calculate the posttest probability of disease is to use the LRs and odds-probability approach.

LRs combine both test sensitivity and specificity into a single measure (a mathematical description of the strength of a diagnostic test), which helps evaluate and interpret a diagnostic test. LRs indicate how many times more (or less) a test result is to be found in persons with disease compared with persons without disease. There are two types of LR—LR positive and LR negative, calculated by the following formulas:

$$\text{LR} = \frac{\text{Probability of result in diseased persons}}{\text{Probability of result in nondiseased persons}}$$

When test results are dichotomized using a single cutoff value to divide "positive" from "negative," every test has two LRs, one corresponding to a positive test (LR^+) and one corresponding to a negative test (LR^-):

$$\begin{aligned}
\text{LR}^+ &= \frac{\text{Probability that test is positive in diseased persons}}{\text{Probability that test is positive in nondiseased persons}}\\
&= \frac{\text{Sensitivity}}{1-\text{Specificity}}\\
\text{LR}^- &= \frac{\text{Probability that test is negative in diseased persons}}{\text{Probability that test is negative in nondiseased persons}}\\
&= \frac{1-\text{Sensitivity}}{\text{Specificity}}
\end{aligned}$$

For continuous measures, multiple interval LRs (iLRs) can be defined to correspond to ranges or intervals of test results. The iLR for a test result interval is the probability of a result in that same interval for a disease-positive patient divided by the probability of a result in the same interval for a disease-negative patient. Given the pretest probability of disease and the test result, the iLR is used to calculate the posttest probability (Table e2–6).

LRs can be calculated using the above formulas. They can also be found in some textbooks, journal articles, and online programs (such as www.thennt.com) (see Table e2–7 for examples). LRs provide an estimation of whether there will be significant change in pretest to posttest probability of a disease given the test result, and thus can be used to make quick estimates of the usefulness of contemplated diagnostic tests in particular situations. An LR of 1 implies that there will be no difference between pretest and posttest probabilities. LRs of > 10 or < 0.1 indicate large, often clinically significant differences. LRs between 1 and 2 and between 0.5 and 1 indicate small differences (rarely clinically significant).

The simplest method for calculating posttest probability from pretest probability and LRs is to use a nomogram (Figure e2–7). The clinician places a straightedge through the points that represent the pretest probability and the LR and then reads the posttest probability where the straightedge crosses the posttest probability line.

A more formal way of calculating posttest probabilities uses the LR as follows:

$$\text{Pretest odds} \times \text{LR} = \text{Posttest odds}$$

To use this calculation formulation, probabilities must be converted to odds, where the odds of having a disease

Table e2–6. Interval LRs for serum ferritin as a test for iron deficiency anemia.

Serum Ferritin (mcg/L)	Interval LR for Iron Deficiency Anemia
≥ 100	0.08

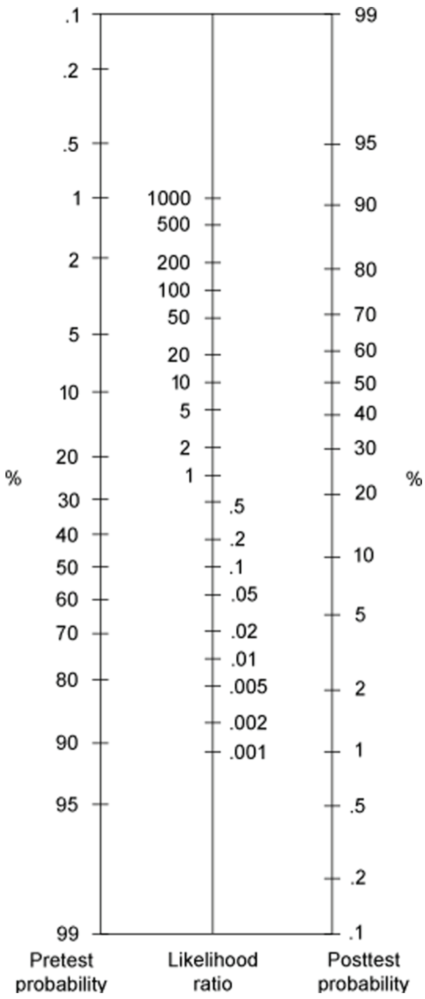

Figure e2–7. Nomogram for determining posttest probability from pretest probability and LRs. To figure the posttest probability, place a straightedge between the pretest probability and the LR for the particular test. The posttest probability will be where the straightedge crosses the posttest probability line. (Adapted from Fagan TJ. Nomogram for Bayes theorem. [Letter.] *N Engl J Med.* 1975;293:257.)

are expressed as the probability of having the disease divided by the probability of not having the disease. For instance, a probability of 0.75 (75%) is the same as 3:1 odds (Figure e2–8).

Odds is defined as the probability of the event occurring divided by the probability of the event not occurring and is calculated by formula **Odds = P/(1 – P)**, where P is the probability of the event occurring. Probability, on the other hand, is calculated by formula **P = Odds/(1 + Odds)**.

To estimate the potential benefit of a diagnostic test, the clinician first estimates the pretest odds of disease given all available clinical information and then multiplies the pretest odds by the positive and negative LRs. The results are the **posttest odds,** or the odds that the patient has the disease if the test is positive or negative. To obtain the posttest probability, the odds are converted to a probability (Figure e2–8).

For example, if the clinician believes that the patient has a 60% chance of having an MI (pretest odds of 3:2) and the troponin I test is positive (LR+ = 24), then the posttest odds of having an MI are

$$\frac{3}{2}\times 24=\frac{72}{2}\text{ or }36:1\text{ odds}$$

$$\left(\frac{36/1}{(36/1)+1}=\frac{36}{37}=97\%\text{ probability}\right)$$

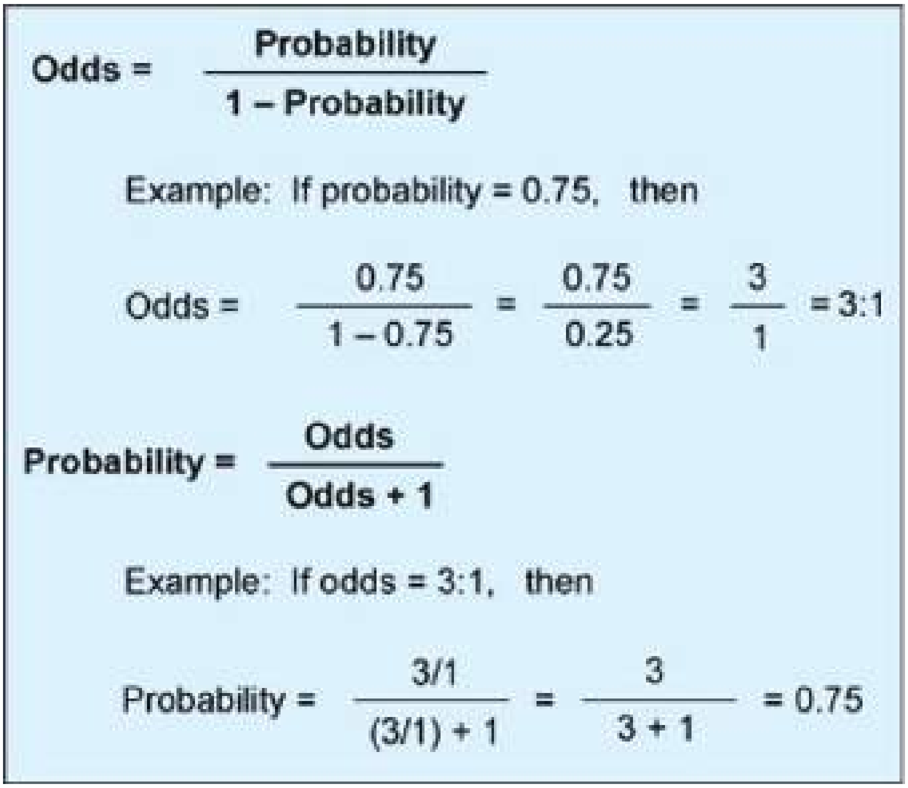
If the troponin I test is negative (LR– = 0.01), then the posttest odds of having an MI are

$$\frac{3}{2}\times 0.01=\frac{0.03}{2}\text{ odds}$$

$$\left(\frac{0.03/2}{(0.03/2)+1}=\frac{0.015}{0.015+1}=1.5\%\text{ probability}\right)$$

SEQUENTIAL TESTING

To this point, the impact of only one test on the probability of disease has been discussed, whereas during most diagnostic workups, clinicians obtain clinical information in a sequential fashion. To calculate the posttest odds after



$$\text{Odds} = \frac{\text{Probability}}{1 - \text{Probability}}$$

Example: If probability = 0.75, then

$$\text{Odds} = \frac{0.75}{1 - 0.75} = \frac{0.75}{0.25} = \frac{3}{1} = 3{:}1$$

$$\text{Probability} = \frac{\text{Odds}}{\text{Odds} + 1}$$

Example: If odds = 3:1, then

$$\text{Probability} = \frac{3/1}{(3/1) + 1} = \frac{3}{3 + 1} = 0.75$$

▲ **Figure e2–8.** Formulas for converting between probability and odds. (Reproduced, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.)

three tests, for example, the clinician might estimate the pretest odds and use the appropriate LR for each test:

$$\text{Pretest odds} \times LR_1 \times LR_2 \times LR_3 = \text{Posttest odds}$$

When using this approach, however, the clinician should be aware of a major assumption: the chosen tests or findings must be **conditionally independent.** For instance, with liver cell damage, AST and ALT enzymes may be released by the same process and are thus not conditionally independent. If conditionally dependent tests are used in this sequential approach, an inaccurate posttest probability will result.

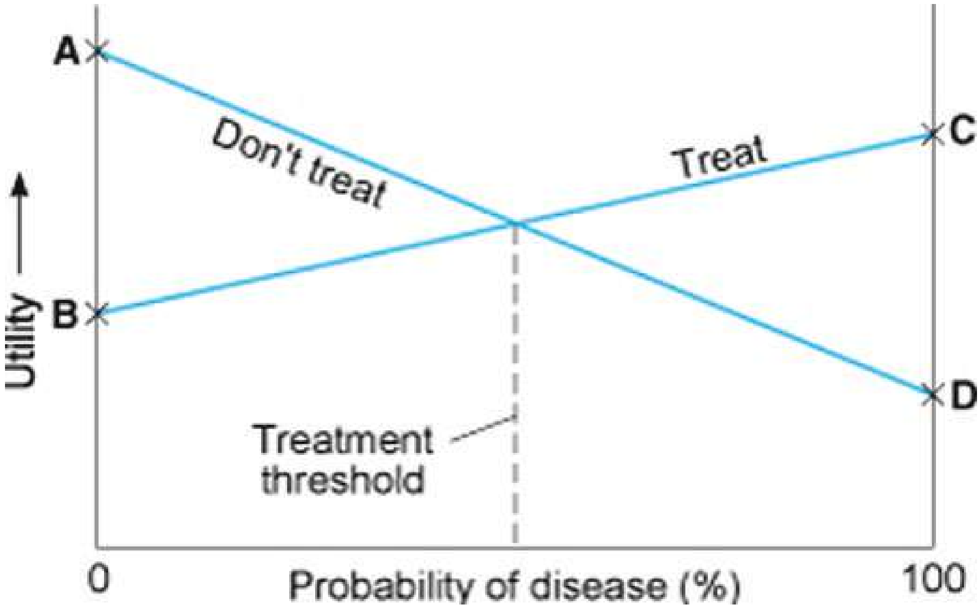
Schlattmann P. Statistics in diagnostic medicine. Clin Chem Lab Med. 2022;60:801. [PMID: 35357790]

THRESHOLD APPROACH TO DECISION-MAKING

A key aspect of medical decision-making is the selection of a treatment threshold, ie, the probability of disease at which treatment is indicated. The treatment threshold is determined by the relative consequences of different actions: treating when the disease is present; not treating when the disease is absent; treating when the disease is actually absent; or failing to treat when the disease is actually present. Figure e2–9 shows a possible way of identifying a treatment threshold by considering the value (utility) of these four possible outcomes.

Use of a diagnostic test is warranted when its result could shift the probability of disease across the treatment threshold. For example, a clinician might decide to treat with antibiotics if the probability of streptococcal pharyngitis in a patient with a sore throat is > 25% (Figure e2–10A).

If, after reviewing evidence from the history and physical examination, the clinician estimates the pretest probability of strep throat to be 15% (ie, clinician's initial assessment), then a diagnostic test such as throat culture (LR+ = 7) would be useful only if a positive test would shift the posttest probability above 25%. Use of the nomogram shown in Figure e2–7 indicates that the posttest probability would be 55% (ie, clinician's new assessment) (Figure e2–10B); thus, ordering the test would be justified since it affects patient management. On the other hand, if the history and physical examination had suggested that the pretest probability of strep throat was 60%, the throat culture (LR– = 0.33) would be indicated only if a negative test would lower the posttest probability below 25%. Using the same nomogram, the posttest probability after a negative test would be 33% (Figure e2–10C). Therefore, ordering



▲ **Figure e2–9.** The "treat/don't treat" threshold. **A:** Patient does not have disease and is not treated (highest utility). **B:** Patient does not have disease and is treated (lower utility than A). **C:** Patient has disease and is treated (lower utility than A). **D:** Patient has disease and is not treated (lower utility than C). (Reproduced, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.)

the throat culture would not be justified because it does not affect patient management.

Tests are only useful if the result is likely to influence or change patient management. The test-treatment threshold is an important concept in clinical decision-making. To apply the threshold model of decision-making, it is necessary to have: (1) validated clinical prediction tools so that pretest probability can be accurately determined from available data; (2) evidence-based treatment threshold for the disease; and (3) accuracy of diagnostic tests, in particular LRs of the tests, in consideration.

Ferraro S et al. Health Technology Assessment to assess value of biomarkers in the decision-making process. Clin Chem Lab Med. 2022;60:647. [PMID: 35245972]

DECISION ANALYSIS

Up to this point, the discussion of diagnostic testing has focused on test characteristics and methods for using these characteristics to calculate the probability of disease in different clinical situations. Although useful, these methods are limited because they do not incorporate the many outcomes that may occur in clinical medicine or the values that patients and clinicians place on those outcomes. To incorporate outcomes and values with characteristics of tests, decision analysis can be used.

Decision analysis is a quantitative evaluation of the outcomes that result from a set of choices in a specific clinical situation. Although it is infrequently used in routine clinical practice, the decision analysis approach can be helpful to address questions relating to clinical decisions that cannot easily be answered through clinical trials.

The basic idea of decision analysis is to model the options in a medical decision, assign probabilities to the alternative actions, assign values (utilities) (eg, survival rates, quality-adjusted life-years, or costs) to the various outcomes, and then calculate which decision gives the greatest expected value (expected utility). To complete a decision analysis, the clinician would proceed as follows: (1) draw a decision tree showing the elements of the medical decision; (2) assign probabilities to the various branches; (3) assign values (utilities) to the outcomes; (4) determine the expected value (expected utility) (the product of probability and value [utility]) of each branch; and (5) select the decision with the highest expected value (expected utility). The results obtained from a decision analysis depend on the accuracy of the data used to estimate the probabilities and values of outcomes.

Figure e2–11 shows a decision tree in which the decision to be made is whether to treat without testing, perform a test and then treat based on the test result, or perform no tests and give no treatment. The clinician begins the analysis by building a decision tree showing the important elements of the decision. Once the tree is built, the clinician assigns probabilities to all the branches. In this case, all the branch probabilities can be calculated from: (1) the probability of disease before the test (pretest probability), (2) the chance of a positive test result if the disease is present (sensitivity), and (3) the chance of a negative test result if the disease is absent (specificity). Next, the clinician assigns value (utility) to each of the outcomes.

Figure e2–10. Threshold approach applied to test ordering. If the contemplated test will not change patient management (as in scenario C), the test should not be ordered. (See text for explanation.) (Reproduced, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.)

After the expected value (expected utility) is calculated for each branch of the decision tree, by multiplying the value (utility) of the outcome by the probability of the outcome, the clinician can identify the alternative with the highest expected value (expected utility). When costs are included, it is possible to determine the cost per unit of health gained for one approach compared with an alternative (cost-effectiveness analysis). This information can help evaluate the efficiency of different testing or treatment strategies.

Although time-consuming, decision analysis can help structure complex clinical problems, assist in difficult clinical decision-making by providers and patients, and improve the quality of clinical decisions. It is particularly useful in situations where diagnostic tests are esoteric or expensive or both (eg, paraneoplastic antibody panel, DNA sequencing–based gene mutation panel for hereditary cancers, etc). Artificial intelligence–based decision analysis algorithms have the potential to outperform traditional tools and are increasingly being integrated into healthcare systems; however, clinicians need to examine the evidence carefully and recognize plausible bias based on full understanding of the training cohorts used to create the algorithms.

EVIDENCE-BASED MEDICINE

Vast resources are being spent on diagnostic testing. New laboratory tests are being developed and marketed all the time, including companion diagnostic tests (tests that are designed to be paired with a specific drug) and DNA/RNA sequencing–based mutation analyses. Direct to consumer tests are gaining popularity among patients and health care providers. Clinicians need to know how to appraise published studies on new diagnostic tests (eg, performance characteristics) and how to determine whether a new test is superior to existing test(s) in terms of clinical utility and cost-effectiveness. Careful examination of the best available evidence is essential.

Evidence-based medicine is the care of patients using the best available research evidence to guide clinical decision-making. It relies on the identification of methodologically sound evidence, critical appraisal of research studies for both internal validity (freedom from bias) and external validity (applicability and generalizability), and the dissemination of accurate and useful summaries of evidence to inform clinical decision-making. Systematic reviews can be used to summarize evidence for dissemination, as can evidence-based synopses of current research. Systematic reviews often use meta-analysis: statistical techniques to combine evidence from different studies to produce a more precise estimate of the effect of an intervention or the accuracy of a test. The concept of evidence-based medicine can be readily applied to diagnostic testing since appropriate use of a diagnostic test is part of the decision-making process.

The Choosing Wisely campaign, launched by the American Board of Internal Medicine in 2012, encourages clinicians and their patients to examine the usefulness of certain laboratory tests and medical procedures, and promotes choosing care that is necessary, evidence- or consensus-based, and not harmful. More than 80 specialty societies have joined the campaign as partners and identified more than 700 tests and procedures commonly used in their respective field that either are considered unnecessary or that should be questioned. Those unnecessary tests and procedures are available online at the Choosing Wisely website (www.choosingwisely.org).

Clinical practice guidelines are systematically developed statements intended to assist practitioners in making decisions about health care. Clinical algorithms and practice guidelines are ubiquitous in medicine, developed by various professional specialty societies or independent expert panels. Diagnostic testing is an integral part of such algorithms and guidelines (eg, high-sensitivity D-dimer test and serum free light chain test in the guidelines for diagnosis and management of VTE and plasma cell myeloma, respectively). Their utility and validity depend on the quality of the evidence that shaped the recommendations, on their being kept current, and on their acceptance and appropriate application by clinicians. Although some clinicians are concerned about the effect of guidelines on professional autonomy and individual decision-making, many organizations are trying to use compliance with practice guidelines as a measure of quality of care. It is important to note, however, that evidence-based guidelines are used to complement, not replace, clinical judgment and shared decision-making tailored to individual patients. Furthermore, personalized treatment (ie, using advanced diagnostic or prognostic tools and incorporating patient preferences to guide an individual patient's treatment) is increasingly recommended as part of practice guidelines. The approach is in keeping with the rapidly evolving field of **personalized medicine,** in which diagnostic testing plays an important role in selecting the best possible therapies that are tailored to individual characteristics of each patient.

Computerized and mobile information technologies provide clinicians with information from laboratory, imaging, physiologic monitoring systems, and many other sources. Computerized clinical decision support systems, along with test order communication systems, have been increasingly used to develop, implement, and refine computerized protocols for specific processes of care derived from evidence-based practice guidelines. Artificial intelligence–based algorithms could help diagnose and manage complicated diseases faster and more efficiently. It is important that clinicians use established information technology to deliver standard medical care in their practice.

Part e3: Information Technology in Patient Care

Overview: Information Technology in Patient Care

e3-01

Russ Cucina

After long trailing other sectors of the economy, health care and health professional education have embraced information technology as a strategic resource in the past two decades. Most of the population uses computers and the internet routinely to manage most aspects of their lives, and patients justifiably expect a comparable level of technological sophistication and online customer service from the health care system. The tremendous potential for information technology in health care, including artificial intelligence, is still in the process of being actualized.

The technical and theoretical details underlying clinical informatics are beyond the scope of this chapter. What follows is a concise introduction to topics and resources of general interest in this field, presented to help clinicians use information technology for the benefit of their patient care.

Lopo C et al. Technology impact on healthcare quality of the hospital: a literature review. Enferm Clin. 2020;30(Suppl 6):81. https://doi.org/10.1016/j.enfcli.2020.06.019, accessed September 4, 2024.

e3-02

Patient Confidentiality & Information Technology

Russ Cucina

The ancient ethical obligation to protect the privacy of our patients takes on new importance in the setting of digital health information. The same ability to make health information universally available that is at the heart of health information technology's power entrains our commitment to patient privacy in new and complex ways. From a legal perspective, in the United States, the security and privacy rules of the Health Insurance Portability and Accountability Act (HIPAA) and the Health Information Technology for Economic and Clinical Health (HITECH) Act place important requirements on the individual clinician and group to ensure the security of electronic protected health information, and several states have enacted more restrictive measures.

Email transmitted by many commercial providers is imperfectly secure, and interception of unsecure email by a malicious third party is easily accomplished with freely available software. Clinicians often incorrectly assume if an email exchange containing protected health information was initiated by the patient, the patient has "consented" to this unsecure communication. However, HIPAA and its related regulations contain no provision for "consenting" to communications that violate its security rule, and patients have no power to relieve clinicians of their obligations under these federal regulations. Further, using a commercial email service for patient communication may constitute a disclosure of that information to that email service provider, itself a privacy violation.

In addition, *HIPAA requires not only secure transmission of protected health information but also secure storage.* Health information stored on a computer, especially a laptop or tablet, is vulnerable to theft either physically or remotely over networks. The potential penalties and costs of remediation, such as notifying affected patients, are significant. Widely reported serious incidents of electronic theft of health information continue notwithstanding public awareness of these risks. Furthermore, some jurisdictions (prominently the Veterans' Health Administration and the state of California) have imposed stricter requirements and higher fines than provided in federal law. Federal regulations make clear that the individual clinician is directly liable for civil and criminal penalties, even if they are acting as the agent or employee of a health system.

Clinicians must take several steps to minimize these risks. *First, clinicians must never use poorly secured, unencrypted email to exchange protected health information, even if the exchange is initiated by a patient.* The preferred solution is to keep electronic exchanges with patients inside a secure electronic health record that provides a portal for the patient to send and receive messages. In the absence of an electronic health record, numerous commercial services developed for health care for secure, private exchange of email are available.

Second, any clinical information stored electronically outside of an enterprise clinical system, such as on an individual computer, laptop, or mobile device, must be both electronically and physically secure. Electronic security includes the correct use of strong passwords, preferably with multi-factor authentication, network firewalls, virus protection, spyware protection, and full-disk data encryption. The security inherent to most consumer-oriented computer hardware and operating systems is not sufficient, and proper security requires considerable technical sophistication. Almost all clinicians should rely on professional services to ensure the security of their computer hardware and data.

Physical security includes preventing direct access to computers or mobile devices that contain health information by unauthorized individuals. Laptop computers are especially risky in this regard, and loss or theft of a laptop containing clinical information, even if only in the form of incidental emails, can have far-reaching legal and financial consequences for an individual clinician and the clinician's employer. Many laptops have the ability to physically encrypt the entire hard drive and require biometric authentication, such as a fingerprint, to gain access. These can offer valuable risk mitigation when laptops are used for clinical work.

Third, the importance of network security continues to be highlighted by high-profile "phishing," "ransomware," and other attacks against organizations' information infrastructure, including high-profile attacks on health care delivery institutions of all sizes. Again, clinicians should rely on professional services to ensure the security of any computer networks for which they have responsibility.

Last, wireless networks in the home or public places are often entirely unsecure, and malicious interception of wireless network traffic is technologically trivial and widely available. Clinicians should never do any clinical work using publicly accessible wireless networks, such as in airports, hotels, or cafés, without an additional layer of network security such as a virtual private network (VPN). At home, clinicians must take appropriate steps to secure a home wireless network before using it for clinical work, which may involve professional consultation with the internet services provider.

e3-03

Clinical Uses of Email

Russ Cucina

Electronic communication can extend and complement direct patient encounters, improve adherence and access to care, and increase patients' involvement in their care. Email is well-suited for communicating administrative information, medication instructions, patient education, routine laboratory results, and appointment reminders. It can augment home monitoring of treatment plans, such as diabetes care or smoking cessation. Clinicians can make announcements to an entire patient population about vacation coverage, influenza vaccination, changes in referral procedures, withdrawal of medications from the market, and other topics (Table e3–1).

However, using email clinically creates legal, ethical, and practical concerns. Email is more permanent than oral communication but can seem more informal than paper correspondence. It is by its nature self-documenting. An email can be duplicated or forwarded with a few keystrokes and inadequate thought, and copies may linger on intermediate or back-up systems long after the sender and receiver have deleted the originals. The casual nature of email in the absence of nonverbal social cues commonly leads to misunderstandings. Email can be easily altered by the sender, the recipient, or a third party, retrospectively and without attribution. It is difficult to positively identify the sender or recipient on either end of an email exchange, and with modest technical expertise it is easy to fabricate an email from most addresses.

Clinicians are sometimes concerned that if their email address becomes widely available, they will be deluged by messages from individuals with whom they have no preexisting therapeutic relationship. Studies have not found the volume of email from unfamiliar patients to be burdensome in practice. However, there is currently no consensus on the clinician's duty in this situation. Additionally, there may be legal consequences to providing advice to patients who are out of state or abroad and thus beyond the scope of the clinician's license. At minimum, clinicians should post electronic communication policies addressing unsolicited communication wherever their email address can be found.

Table e3–1. Some suggested uses of patient-clinician email (listed in alphabetical order).

Electronic Health Records

Russ Cucina

e3-04

The effective use and interoperability of electronic health records continues to be a central public policy priority in the United States and around the world. The enthusiasm stems from *the potential of electronic health records to provide large-scale improvements in the efficiency, safety, and cost-effectiveness of health care*. Mature products are available catering to the needs of individual clinicians, group practices, and large integrated delivery networks. Systems range from large-scale solutions to operate every aspect of an integrated delivery system, to software-as-a-service offerings for the solo practitioner, to targeted systems for specific subspecialties.

Clinicians and health systems often focus heavily on the selection of appropriate software when planning to adopt an electronic health record. Although appropriate software is critical, the challenge of adopting a new electronic health record is not primarily one of technical implementation, but rather the major challenges in process redesign, understanding and supporting workflows, and economic and social aspects of organizational change. A widely cited 2005 study by RAND estimated $77 billion in annual cost savings in the United States if electronic health records were broadly adopted and the National Academy of Medicine has published a standard framework for assessing their return on investment at the organizational level.

In part to assist purchasers in selecting clinical software meeting a baseline set of functional requirements, the United States has enacted a variety of incentive-based programs, beginning with the 2009 HITECH Act and the "Meaningful Use" program, and subsequent successor programs and standards such as the Cures Act and the Promoting Interoperability Program. Physicians and medical groups who use an electronic health record and participate in these programs should keep current with the bulletins of the Office of the National Coordinator for Health IT at HealthIT.gov, particularly the subsection under "Laws, Regulation, and Policy." Electronic health records remain a point of vigorous debate at the federal level, and substantial policy changes may continue, with the prospect of further impact to federal electronic health record policies and incentive programs.

The challenge of workflow analysis and organizational change is a topic of ongoing industry and research interest and is necessarily local to each care setting. Many consulting firms specialize in health care information technology transformation or have health care information technology practices to provide assistance. The roles of Chief Health, Medical, and Nursing Information Officers in health systems reflect the need for leadership that spans the clinical enterprise, as information technology departments are counted among the clinical service providers alongside radiology and the laboratory. Currently, some of the most successful clinical software vendors distinguish themselves in part by providing a template for leadership in organizational change as a package with their software products.

e3-05

Computerized Provider Order Entry

Russ Cucina

Of the many components that make up a clinical information system, perhaps the greatest value has been ascribed to *computerized provider order entry (CPOE)*. CPOE substantially eliminates the problems of legibility, ambiguous abbreviations, and delays in order communication, and should offer automated dose checking, drug-drug interaction checking, drug-allergy checking, guideline promotion and standardization of care, and other more sophisticated forms of real-time clinical decision support. The evidence for the benefit of CPOE is considered solid, in addition to the face value improvement of order quality and communication speed.

CPOE systems have enjoyed many well-studied successes; most US hospitals installed CPOE in response to the HITECH Act incentives and penalties. Adopting and maintaining CPOE is a substantial challenge, however, and there were a handful of spectacular failures. As with electronic health records generally, the challenge is less one of technology but rather of accurate and complete support of clinician workflow, attention to system usability, social and organizational factors, and adequate training and support. Furthermore, there have been controversial reports of degradation in patient safety indicators subsequent to the installation of CPOE systems. These reports underscore that any transformational change in the process of care delivery necessarily contains hazards. The fact that CPOE has demonstrated benefits across many settings does not guarantee it will be beneficial in all implementations in all places. Software systems that account for the workflow and usability challenges and vendors that provide customers not only with software but also with outstanding implementation guidance and support will continue to thrive.

Clinical Decision Support & Artificial Intelligence

e3-06

Russ Cucina

In contrast to clinical reference material, such as continuously updated online journals and medical texts, computerized clinical decision support directly assists the clinician in making decisions about a specific patient. Decision support does not need to be sophisticated to have significant impact. For example, simple dose-range checking for medications, drug-drug interaction checking, and drug-allergy checking are conceptually straightforward but can catch a critical source of human error that no amount of training or personal vigilance can entirely eliminate. Slightly more advanced are systems that analyze clinical data (such as calculating a creatinine clearance) and present guidance based on those data. More sophisticated systems look for trends in values, such as the rate of fall of the hematocrit or the rising body weight of an ICU patient who is accumulating extracellular fluid, where an absolute number may not be notable, but an alert to the trend may be important and prompt action.

Decision support is challenging to implement and maintain. *The most vexing problem is "alert fatigue."* Studies within and outside health care show that the benefit of an alert, such as a pop-up interaction in a software system, is rapidly extinguished if the alert becomes a routine part of using the system. A familiar clinical example is the minimal attention paid to most audible alerts produced by cardiac telemetry systems. If a clinical decision support in a CPOE system provides an "alert" to the drug-drug interaction of two medications routinely used together safely, such as enoxaparin and warfarin, in the same way as to unfamiliar but dangerous interactions, such as theophylline and fluoroquinolones, clinicians become desensitized to the alerts and dismiss critically important guidance when it does appear. Alert fatigue is a fact of human cognition and cannot be eliminated through training, education, or self-discipline. The best clinical systems offer fine-grained tuning of the system's behavior, such as altering the system's response by drug and provider specialty, and offer a range of interruptive and noninterruptive support mechanisms. The price of this flexibility is the institutional effort required to design and maintain the system. However, even these measures have yet to demonstrate consistent improvement in the effectiveness of alerts.

The most complex decision support systems attempt to aid clinical diagnosis. The application of artificial intelligence (AI) to medicine has a long history; however, most diagnostic expert systems have been stand-alone, requiring effort by the clinician outside of their normal workflow, and have thus had limited clinical implementation. Examples of clinical diagnostic systems directly imbedded in an electronic health record are few but are an area of ongoing research and commercial interest (Table e3–2). Most successes have been in detection of specific clinical syndromes, such as the early deterioration of sepsis in hospitalized patients, and the promise of a "generalized artificial intelligence" for unbounded diagnostic problems remains to be realized.

The class of artificial intelligence methods known as Large Language Models (LLMs) have garnered significant attention for their ability to appear to recreate human knowledge through a natural language interface. These models are typically built by having a computational neural network consume a very large corpus of textual material, creating a computational model of the knowledge contained in the corpus. The LLM is then able to craft responses to open-ended queries based on the information encoded in the model. LLMs can have a remarkable ability to appear to recall and synthesize information, including generation of human-like speech and writing, as well as visual images, synthesized speech, and other media. The current generation of generalist LLMs have primarily been trained on publicly available internet content and have not been trained specifically on medical corpora. While they show an impressive ability to pass simulated multiple-choice exams or to choose among prespecified diagnostic possibilities, their applicability and reliability to unbounded real-world clinical problems remains under exploration.

Additionally, the ability of LLMs to produce human-like written language is seeing their application as "AI Scribes," where an LLM listens to a live clinical interaction, or reads a patient query in an online portal, and drafts a proposed clinical documentation of the encounter, or response to the patient query. The potential for "AI Scribes" to offload some of the burden of clinical documentation from clinicians is proving significant and is a rapidly developing area.

Table e3–2. Functional classes and examples of clinical decision support systems (listed in alphabetical order).

Class	Function	Examples
Communication	Alert clinician and other providers who need to know about unusual data (eg, test results) or communications regarding specific patients	Parameter alerts provide clinicians with key information on panic values. Automated emails send information to specified clinicians when certain clinician patient encounters occur (eg, email to primary doctor when patient is evaluated in the emergency department).
Data organization	Organization and presentation of disparate data into logical, intuitive schemas at the point of need	Aggregate data trending observes key indicators for large numbers of patients over time (eg, emergence of antibiotic resistance patterns).
Expert advice	Diagnostic and therapeutic advice using a comprehensive knowledge base and a problem-solving method, such as probabilistic reasoning, neural nets, or heuristic rules	Differential diagnosis and suggestions for further testing generated from patient-specific data. Reducing uncertainty in test interpretation (eg, probability of pulmonary embolism given patient demographics and indeterminate ventilation-perfusion scan).
Feedback	Provide feedback by responding to an action taken by the clinician or to new data entered into the system	Drug family checking results in alerts on allergies, drug-drug interactions, and other patient-specific conflicts. Parameter checking looks for dosing errors and other parameter discrepancies in patient-specific scenarios (eg, gentamicin dosing in CKD). Redundant utilization checking alerts physicians to duplicate test orders.
Intelligent actions	Automation of routine and repeated tasks for the clinician on a regular time schedule (eg, provision of all new laboratory values on current patient lists every morning)	Rule-based event detection allows users to create logical rules to be checked when triggering events occur (eg, check glucose level in hyponatremia). Time-based checks to post reminders when expected transactions have not occurred (eg, warfarin order not filled by 8:00 PM).
Proactive information	Provision of information to the clinician at the point of need (eg, clinical pathway for pneumonia when patient with pneumonia is being admitted to hospital)	Template and order sets can be provided to given situations.

Social Media & Online Presence in Clinical Practice

Russ Cucina

Many clinicians, either individually or through their practice group, maintain a website or social media presence as a service to their patients. For the individual practitioner or small group, very affordable web authoring and hosting services are available commercially. Large groups and institutions typically maintain their own websites and assist individual providers in representing themselves in a standardized way. Offering clinical information to patients or communicating patient-related health information over the internet requires consideration of ethical and legal issues. Providing medical content can be construed as formal medical advice. As always, general patient education material and online recommendations should be followed by instructions directing patients to first discuss any suggested lifestyle or medication changes with a clinician before adoption. *Clinicians and clinical students should never post about clinical cases on social media, including even if they have attempted to anonymize the information.* Clinical details about a case are often sufficient to reconstruct the identity of the involved patients, violating the patients' privacy and risking professional and legal repercussions to the clinician or student.

Many clinicians use online resources for references and to obtain continuing medical education. Numerous high-quality medical news websites are available, and most medical journals offer direct access to current and archived issues to individual subscribers and institutions. Websites specifically aimed at clinicians provide a constantly expanding repository of information, and several websites have established a favorable brand reputation.

Informal consultations among clinicians are common, but historically had been limited to the offices and conference rooms within a health care setting or at periodic academic meetings. The internet and its dramatic reduction in barriers to communication have made these activities continuous and far-reaching. Many online discussion forums are available for health care providers with similar interests. A prominent example is Patients Like Me, http://www.patientslikeme.com/, which caters to the public and provides forums for a variety of chronic diseases, while Sermo, http://www.sermo.com/, and Doximity, http://www.doximity.com/, are directed at physicians. Some require registration demonstrating credentials (eg, medical license number), and moderators may monitor postings for accuracy and relevance.

Lastly, messaging applications allow real-time, synchronous text chat and file exchange with other online users, such as patients and other clinicians. Clinicians should remember that although messaging applications provide the appearance of a private discussion, those systems broadly used by consumers are often not secure and may not provide suitable security for discussion of confidential information.

Telemedicine

Russ Cucina

The SARS-CoV-2 pandemic produced an explosion in the use of telehealth worldwide. In the United States, video visits that had previously not been reimbursed by government-sponsored payment programs became reimbursable for the duration of the public health emergency and has since been twice extended. As of February 2025, definitive congressional action to make this reimbursement permanent is pending and uncertain.

Telemedicine is the use of information and communications technologies to provide health care when distance separates the participants. Clinicians have been practicing telemedicine over the telephone since the telephone was invented. The current generation of telemedicine applications expands the remote clinician's capabilities beyond diagnosis to therapeutic interventions. Telesurgery, remote psychotherapy, and virtual home visits to manage chronic medical problems have all been demonstrated, although prior to the SARS-CoV-2 global pandemic, deployment had grown only modestly in most regions. Multiple websites describe these and other innovative uses of telemedicine for interested clinicians to explore (Table e3–3).

The global SARS-CoV-2 pandemic produced in many countries an explosion in the use of telehealth, as restrictions on local travel, and the desire to keep patients physically separated from one another and from their clinicians, made real-time video care an essential tool. As patients adopted video teleconferencing software for education, work, and socialization, this familiarity with the technology had positive spillover effects on their willingness to use these same technologies to receive health care.

As video visits have become an established practice, the limitations on a "mostly video" care relationship have become increasingly apparent. Much of the physical examination, particularly in otolaryngology, ophthalmology, and dentistry, remains impractical or virtually impossible to perform remotely. In addition to the obvious need to be "in person" for phlebotomy, electrocardiography, or other procedures, concerns have arisen about whether some diagnostic testing (eg, cancer screening) or another vital health care maintenance procedure (eg, scheduled vaccination) may be underutilized because it seems comparatively inconvenient. The net effect of the substitution of in-person ambulatory care by telehealth on long-term health outcomes remains to be elucidated and may vary according to the patient population and specialty area.

However, a burgeoning industry that increases options for what is possible in remote care emerged. Remote measurement and transmittal of vital signs, remote blood pressure monitoring, and instrumented pulse oximetry and continuous glucose monitoring are moving from niche applications to the mainstream with their sudden adoption in video care. Other aspects of practice management, such as completion of forms, scheduling, and follow-up, have followed the actual visit in being moved to "virtual" platforms, making remote care more complete and more sustainable.

Although information transfer ignores geographic boundaries, medical licensure does not always do so—especially in the United States, where several states have explicitly limited the interstate practice of telemedicine. Liability and malpractice are thorny issues, as the practice of telemedicine presents a new form of the patient-caregiver relationship and associated hazards, such as technical failures leading to suboptimal or altered data.

Table e3–3. Examples of current telemedicine applications (listed in alphabetical order).

Directly observed therapy for tuberculosis
Home fetal monitoring during complicated pregnancies
In-flight emergency resuscitation guidance on commercial aircraft
Monitoring compliance with home drug dispensers
Preoperative screening and postoperative follow-up of patients of surgeons on service missions to developing nations
Providing specialty care to incarcerated individuals
Remote dermatologic, pathologic, or radiographic consultations
Remote monitoring of ICU patients by intensivists
Teleproctoring laparoscopic surgery

Part e4: Podiatric Disorders

e4-01

Bunion

Monara Dini
Charles B. Parks

ESSENTIALS OF DIAGNOSIS

- Bony bump at the base of the big toe.
- Swelling, redness, or pain at the base of the big toe.
- Difficulty with shoe wear.

GENERAL CONSIDERATIONS

A **bunion** is one of the most prevalent foot problems seen by foot and ankle specialists. Bunion is a deformity at the first metatarsophalangeal joint with abduction and valgus rotation of the great toe combined with a medially prominent first metatarsal head (Figure e4–1A). Bunions form when there is a disruption of the balance of forces on the tendons that cross the big toe joint. The first metatarsal head is susceptible to external forces because it has no muscular insertion. As the big toe deviates in a lateral direction, the adductor hallucis and flexor hallux brevis muscles serve as deforming forces as their pull shifts lateral to the longitudinal axis of the big toe joint. As the deformity progresses, the lateral soft tissues become contracted while the medial tissues become attenuated. It is considered to be a progressive deformity.

Five types of conditions can lead to a bunion deformity: (1) arthritic conditions, (2) biomechanical abnormalities, (3) neuromuscular diseases, (4) genetic disorders, and (5) trauma. Abnormal foot mechanics that may contribute to a bunion deformity include equinus contracture and pes planus. Neuromuscular disease that can contribute to a bunion deformity includes cerebral palsy or cerebrovascular accident. Bunions may be associated with certain types of inflammatory arthritic conditions, such as rheumatoid arthritis. Genetic disorders that may lead to ligamentous laxity and subsequent instability leading to bunion deformity include Ehlers-Danlos syndrome, Down syndrome, and Marfan syndrome. Amputation of the second toe may increase the risk of developing a bunion deformity due to the loss of the lateral buttress that the second toe provides the big toe.

Any disorder that results in excessive amount of pronation can predispose a person to bunion development. Therefore, ***biomechanical control*** of the foot is particularly important in preoperative and postoperative settings. Patients with this deformity often have a significant family history of bunion deformity. Although bunions tend to run in families, it is the foot type that is passed down and not the bunion. The deformity is more prevalent in women and is likely caused by wearing narrow footwear. Controversy remains, however, regarding the effects of heredity and shoe style as precursors to bunion deformity. What is known is that an abnormal foot structure, such as pes planus (flat foot), increases the incidence of bunion deformities.

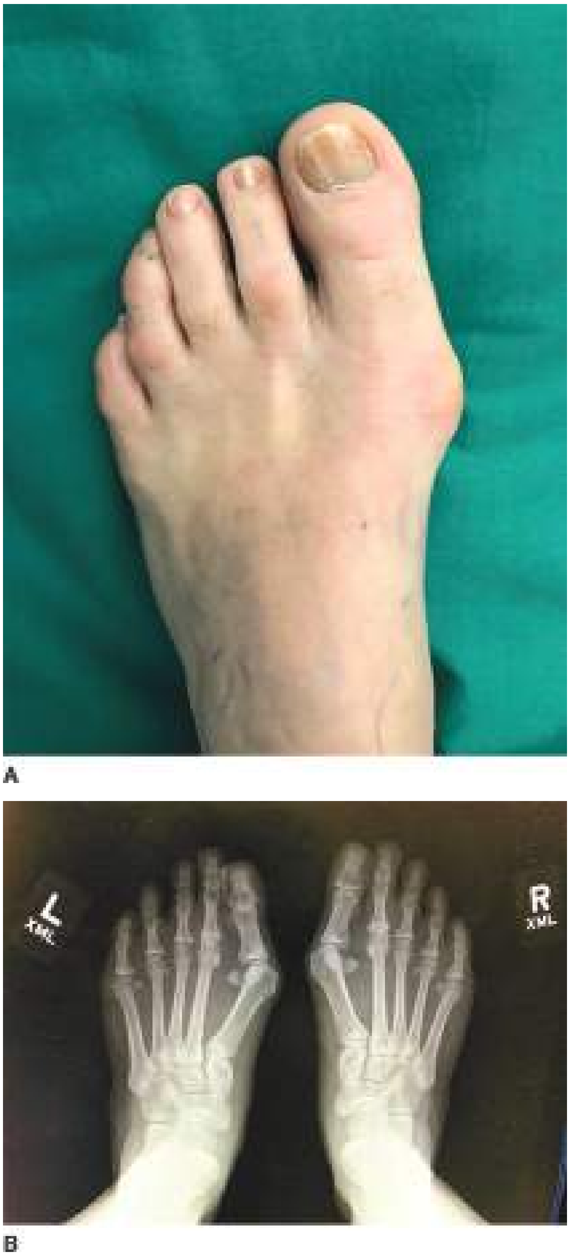
CLINICAL FINDINGS

A. Symptoms and Signs

Bunions may or may not be symptomatic. Pain varies with the severity of the deformity. When symptoms are present, patients frequently report dull achy pain, swelling, and redness at the site of the bunion that are exacerbated with walking and narrow shoes but relieved with rest. A burning sensation is characteristic of an adventitious bursa (a fluid-filled sac that arises in the soft tissue due to repeated shearing forces) that may form on the medial aspect of the big toe joint. Chronic pressure to the outside of the big toe will cause irritation of the first proper digital nerve, leading to paresthesia or neuralgia of the big toe. The clinical examination entails inspecting the foot type, the patient's gait, and the foot (weight-bearing and non–weight-bearing). There is a variable spectrum of presentation of the deformity from mild bony prominence to severe dislocation of the big toe joint. Painful or limited motion of the big toe joint is indicative of degenerative arthrosis. Other associated signs include intractable plantar keratosis under the second metatarsal head, interdigital neuromas, lesser deformities, and callus.

B. Imaging

Plain radiographs are used to determine the severity of a hallux valgus deformity. Weight-bearing anteroposterior



▲ **Figure e4–1.** **A:** External examination shows deformity of the big toe joint. **B:** Radiograph is necessary to evaluate the extent of the deformity. (Used, with permission, from M. Dini, DPM.)

and lateral radiographs of the foot are the most useful images (Figure e4–1B).

Oblique views or sesamoid axial views of the foot may aid in recognizing other deformities. Plain radiographs, in conjunction with the clinical findings, are used to determine various angular relationships that allow the clinician to classify the severity of the deformity as mild, moderate, or severe. This classification of bunions can serve as a guideline for treatment of the deformity.

TREATMENT

A. Conservative

Conservative care entails *patient education* of the natural history of the deformity and *biomechanical support* and is often adequate to relieve symptoms. Biomechanical support includes a custom or prefabricated orthotic device or supportive shoes. Orthotics can provide support and improved motion for bunion deformities associated with pes planus or ligamentous laxity. Shoe modifications such as pocketing of the medial shoe counter, soft leather material, or simply wider shoes may provide symptomatic relief of pressure points over the bunion. Other palliative forms of conservative management include spacers, pads, and splints that are commercially available.

In adventitious bursitis, anti-inflammatory medications such as NSAIDs may provide symptomatic relief.

It is important to note that conservative treatment provides a degree of symptomatic relief but does not reverse the bunion deformity.

B. Surgical

Pain and discomfort unresponsive to conservative care are the primary considerations for surgical correction. Over 100 different surgical treatments have been described in the literature to correct bunion deformities.

As a general guideline, *the severity of the deformity dictates the type of surgery.* Mild to moderate bunion deformities are managed with distal metatarsal osteotomies, whereas severe deformities are managed with more proximal osteotomies. Fusion of the first metatarsophalangeal (MTP) joint is reserved for a bunion deformity associated with significant arthrosis of the big toe joint, severe deformities, or salvage of failed previous bunion procedures.

WHEN TO REFER

- If the patient has not responded to conservative treatment.
- There is severe deformity (overriding toes).
- There is severe pain from the MTP joint or bunion.

Hammertoe

Monara Dini
Charles B. Parks

e4-02

ESSENTIALS OF DIAGNOSIS

- The toe is bent at the middle joint resembling a hammer.
- Corns or calluses on top of the middle joint of toe, between toes, or on tip of toe.
- Pain or irritation to toe when wearing shoes.

GENERAL CONSIDERATIONS

Hammertoe is a painful contracture of the second, third, fourth, or fifth toes. It can result from improperly fitting shoes (ie, too short or narrow), trauma, or a muscle/tendon imbalance.

Muscle/tendon imbalance is the most common cause of hammertoe. Structural changes in the foot can lead to a muscle/tendon imbalance, leading to the contracture of the toes. More specifically, the muscle/tendon imbalance can fall into three major categories: flexor stabilization, flexor substitution, and extensor substitution. **Flexor stabilization** generally presents in a pronated foot type as the flexor muscles gain mechanical advantage over the interossei muscles. **Flexor substitution** is the least common cause but presents in the supinated foot type due to the weakness of the triceps surae, which leads to substitution from the deep posterior and lateral muscle groups. **Extensor substitution** generally presents in the supinated foot type and occurs during the swing phase of gait as the extensor digitorum longus tendon overpowers the lumbricales. A hammertoe can be found in conjunction with or worsened by a bunion.

Narrow or high-heeled shoes can push toes into a bent position. If a toe remains bent for an extended period, the muscle tightens and cannot stretch back. Women are more likely to be affected with hammertoes due to improperly fitting shoes.

Hammertoe is a progressive deformity. It begins as flexible in the earlier stages and worsens over time, leading to a rigid deformity. In more severe presentations of hammertoe, ulcerations can develop.

CLINICAL FINDINGS

A. Symptoms and Signs

The presenting symptoms of hammertoe include contracture of the toe at the proximal interphalangeal (PIP) joint that leads to pain and irritation when wearing shoes. There can also be associated buildup of corns and calluses at the location of the contracture. The most common symptom is redness or burning sensation.

A hammertoe deformity can be categorized as either flexible, semi-rigid, or rigid. The flexible hammertoe deformity has mobility at the PIP joint. The rigid hammertoe deformity is immobile at the PIP joint.

B. Imaging

Plain radiographs are used to determine the severity of the hammertoe. Weight-bearing anteroposterior and lateral views are the most useful images. The radiographic images demonstrate dorsiflexion of the proximal phalanx with plantar flexion of the intermediate phalanx. In more severe cases, the joint illustrates signs of adaptation, including degeneration of the PIP joint or even dislocation of the MTP joint.

TREATMENT

A. Conservative

Initial treatment consists of wearing shoes with a soft, deep, and wide toe box. Patients should avoid tight or narrow shoes, such as high heels. A shoe repair shop may be able to stretch the toe box of certain shoes to provide relief of irritation to the toes. A custom orthotic in the shoe is also helpful to control the muscle/tendon imbalance.

A *Budin splint* or *crest pad* can be used to shield the hammertoe and force the muscles of the toe to stretch. In addition, over-the-counter pads may be placed over the corns to reduce the amount of irritation.

Injection of corticosteroids or oral/topical NSAIDs may reduce swelling and pain.

B. Surgical

Surgery is recommended when the condition has progressed or conservative treatment has not yielded pain relief. The type of surgical treatment depends on the severity of the deformity.

A flexor tenotomy can be considered for a reducible hammertoe in a medically compromised or older patient. It provides a minimal incisional approach with minimal postoperative recovery.

A PIP joint arthroplasty can be considered for a semi-reducible or rigid deformity of the PIP joint. This procedure corrects the deformity by shortening the phalanx.

Arthrodesis (fusion) of the PIP joint should be considered for a semi-rigid or rigid deformity of the PIP joint. It is the procedure of choice when there is an associated neurologic dysfunction.

WHEN TO REFER

- If the patient has not responded to conservative treatment.
- There is severe deformity.
- There is severe pain or ulceration from the deformity.

Ceccarini P et al. Clinical comparison between shortening osteotomy of the proximal phalanx neck and arthrodesis in hammer toe surgery at mid-term follow-up. J Foot Ankle Surg. 2019;58:221. [PMID: 30553747]

Hallux Limitus

Monara Dini
Charles B. Parks

e4-03

ESSENTIALS OF DIAGNOSIS

- Loss of motion in the first MTP joint.
- Pain and stiffness in the big toe during activity.
- Pain and stiffness aggravated by cold weather.
- Swelling and inflammation around the joint.
- Hallux rigidus (the end-stage form of hallux limitus) indicates loss of motion of the MTP joint.

GENERAL CONSIDERATIONS

Hallux limitus is a painful, acquired, progressive arthritic condition of the first MTP joint. Hallux limitus occurs in three groups: congenital, adolescents, and adults. Hallux limitus can present unilaterally or bilaterally, but the condition in both feet may not occur at the same stage of arthritis.

Multiple direct and indirect causes of adult hallux limitus have been proposed. Direct mechanisms include trauma, fractures, or turf toe sprains. Indirect forces include biomechanical deformities of the medial column of the foot. Aside from osteoarthritis, various associated factors have been implicated in the etiology of hallux limitus, including inflammatory diseases such as rheumatoid arthritis and gout.

Hallux limitus is a condition that can worsen with time and lead to the condition **hallux rigidus.** Hallux rigidus, the condition in which there is little or no motion of the big toe joint, is considered to be the end-stage form of hallux limitus.

CLINICAL FINDINGS

A. Symptoms and Signs

The presenting symptoms of hallux limitus are variable and commonly include pain, stiffness, or limited motion of the hallux. The symptoms appear gradually with a deep and achy pain as the most frequent presentation. The degree of discomfort usually correlates with the activity level such as bending, walking, and standing and tends to progressively increase throughout the day.

Often, the pain and stiffness are exacerbated in cold temperatures. Symptoms vary depending on stage and are aggravated by activity and footwear. Most often the formation of a dorsal bone spur around the big toe joint will lead to direct pressure against the shoe and exacerbate the pain or result in callus formation. In addition, symptoms of paresthesia or neuralgia to the big toe may develop secondary to chronic pressure from the bone spur. Pain is exacerbated by shoes that lack support or drive the big toe joint into dorsiflexion beyond its limited range of motion (ie, high heels or flip flops). Pain, swelling, and crepitus with activity and walking can be encountered in the MTP joint. With time, the mobility of the big toe joint diminishes and dorsiflexion becomes limited.

Most patients exhibit pain in other parts of the body including mid-foot, ankle, knee, and hip secondary to an altered gait pattern.

B. Imaging

Plain radiographs are used to determine the type and severity of arthritis, but the pain may not coincide with the radiographic findings. Weight-bearing anteroposterior (Figure e4–2A) and lateral views are the most useful images (Figure e4–2B). The degree of involvement is classified into four stages. **Stage I** is a mild disease with minimal adaptive changes, but patients may feel pain at the end of the range of motion. **Stage II** is defined as moderate hallux limitus with bone spur formation displaying signs of joint adaptation. **Stage III**, severe hallux limitus, is associated with joint deterioration and pain on full range of motion. Stage III displays significant loss of cartilage on radiographic imaging. **Stage IV**, better known as **ankylosis**, indicates obliteration of the joint space. Patients with stage IV disease have severely limited or no motion at the big toe joint.

TREATMENT

A. Conservative

Treatment for mild or moderate cases may include over-the-counter measures, but these measures may not stop progression. NSAIDs may help reduce swelling and pain.

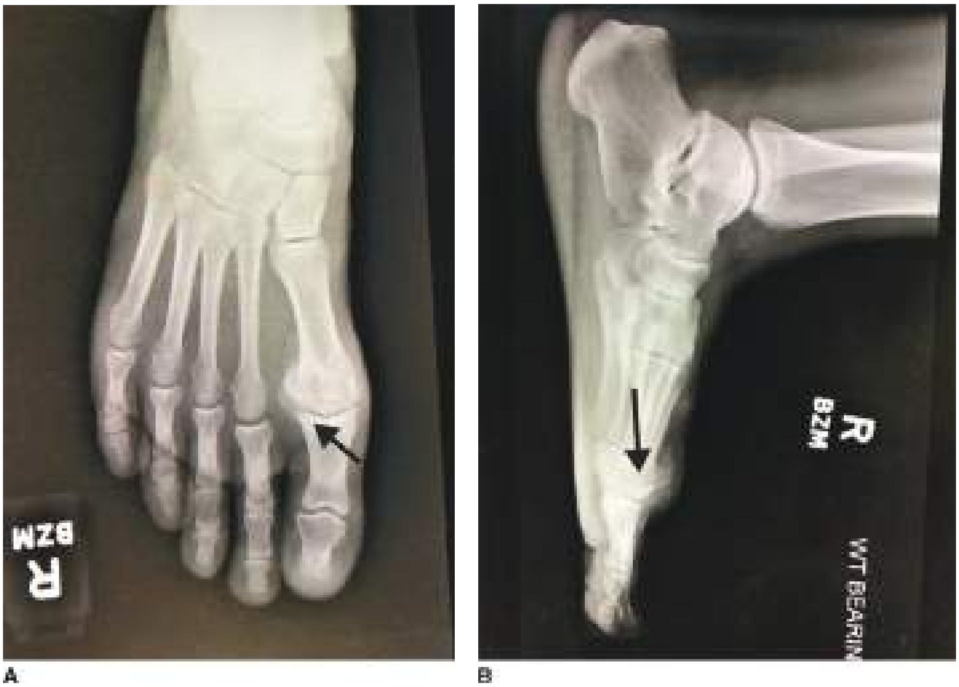

Figure e4–2. Two radiographs showing hallux limitus. (Used, with permission, from M. Dini, DPM.)

The application of ice packs or contrast baths helps reduce inflammatory symptoms. Wearing a shoe with a wide toe box reduces the amount of pressure on the toe. A stiff-sole or rocker-bottom–soled shoe helps decrease the pressure put on the big toe when walking. Custom orthotics with reverse Morton extension or Morton extension help eliminate the amount of bend in the big toe. Injection of corticosteroids may reduce swelling and pain. Ultrasound therapy or physical therapy may reduce inflammatory symptoms and provide better motion at the big toe joint.

B. Surgical

Surgery is recommended in patients whose condition has progressed or who have gotten no pain relief from conservative treatment. The type of surgery is based on the stage of hallux limitus. Stage I is treated with conservative measures. **Cheilectomy** is recommended when damage is mild or moderate, such as in stage II. It entails the removal of bone spurs and reshaping the first metatarsal head to allow the toe more room to bend. Stage III hallux limitus may be treated with an osteotomy to reposition the remaining cartilage of the first metatarsal head or a hemi-implant, or both. Stage IV may be treated with arthrodesis (fusion) or arthroplasty. Arthrodesis involves fusing the bones together when the damage to the cartilage is severe. Once the damaged cartilage is removed, the bone is permanently fused with hardware. The patient will not be able to bend the toe at all. Arthroplasty entails the removal of bone from the joint (resection) with or without an implant. Joint resection is the procedure of choice in older or lower functional demand patients.

WHEN TO REFER

- If the patient has not responded to conservative treatment.
- There is severe pain from the MTP joint or bunion.

Fifth Metatarsal Fracture

Monara Dini
Charles B. Parks

e4-04

ESSENTIALS OF DIAGNOSIS

- Pain to the lateral border of the foot.
- Swelling and ecchymosis to the lateral aspect of the foot.
- Difficulty with weight bearing.
- Injury (inversion injury of the ankle, blunt trauma).

GENERAL CONSIDERATIONS

The fifth metatarsal is the most commonly fractured metatarsal. The fifth metatarsal can be divided anatomically into tubercle, base, shaft, head, and neck. Distal fifth metatarsal fractures involve the distal shaft, head, and neck region. Fractures of the base of the fifth metatarsal are more common than distal fractures. Proximal fifth metatarsal fractures are separated into three zones: (zone 1) tuberosity avulsion fracture, (zone 2) Jones fracture, and (zone 3) diaphyseal stress fracture.

Tuberosity avulsion fracture of the fifth metatarsal is also known as the "tennis fracture." It is the most common type of proximal fifth metatarsal fracture. The mechanism of this fracture pattern remains controversial; it may be caused by a violent contracture of the peroneus brevis muscle during sudden inversion or by avulsion by the lateral band of the plantar fascia.

Jones fracture mechanism of injury is an adduction force applied to the foot while the ankle joint is plantar flexed. Jones fracture occurs in a *vascular watershed area*, which is at a higher risk for nonunion than the zone 1 fracture. A Jones fracture has a higher incidence in the athletic (ie, football or basketball) or active population. It generally presents acutely in nature and has a nondisplaced fracture pattern.

Diaphyseal fifth metatarsal fractures are most commonly *stress induced*. The mechanism of injury is from repeated distractive forces, an increase in activity, or extensive sports practice. Both structural and biomechanical abnormalities can lead to the repetitive load concentrations. Diaphyseal stress fractures also have an increased risk of nonunion due to close proximity to the watershed area of the fifth metatarsal. A higher incidence of stress fractures can be seen in patients with pes cavus, metatarsus adductus, Charcot foot, and Charcot-Marie-Tooth disease.

CLINICAL FINDINGS

A. Symptoms and Signs

All fifth metatarsal fractures present with pain to the lateral border of the forefoot and difficulty with weight bearing. If the fracture is acute, there is associated swelling and ecchymosis.

The symptoms of stress fracture differ from those of a Jones fracture. Stress fracture displays a prodromal symptom of dull, aching pain that is associated with activity but often without an acute, inciting event.

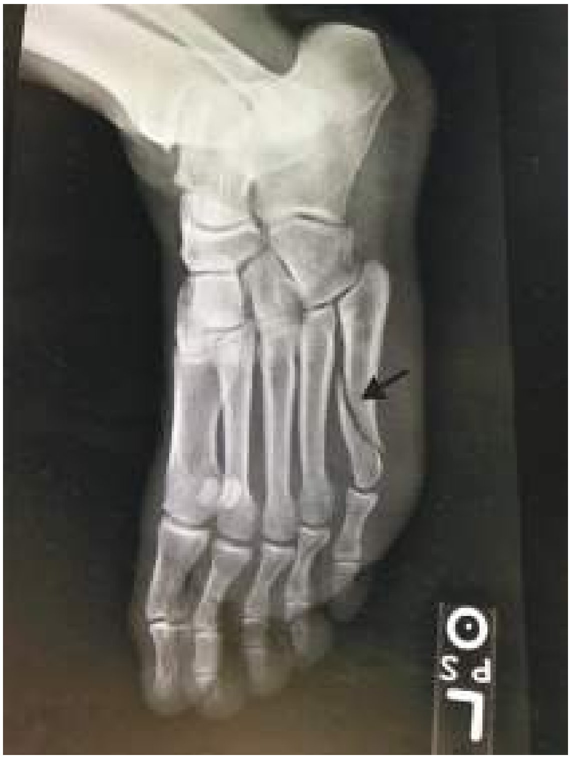
B. Imaging

Plain radiographs should be obtained to diagnose a fifth metatarsal fracture, including anteroposterior, lateral, and oblique foot images (Figure e4–3).

Zone 1 fracture pattern is extra-articular and involves the tuberosity or styloid process. This fracture pattern is often associated with a lateral ankle sprain. Therefore, the **Ottawa ankle rules** should be followed, which include obtaining foot radiographs in patients with ankle inversion injuries who also have associated midfoot pain and bony tenderness to the navicular and the base of the fifth metatarsal as well as those who are unable to bear weight.

Zone 2 is a transverse fracture located at the diaphyseal-metaphyseal junction approximately 1.5 cm from the tuberosity. It usually involves the fourth and fifth intermetatarsal articular facets.

Zone 3 fracture is located in the proximal diaphysis of the fifth metatarsal and distal to the fourth to fifth metatarsal articulation. However, plain radiographs may not show a fracture early in the process; the fracture may not be evident for up to 3 months. Other imaging modalities, such as MRI and bone scan, can help with earlier detection of a stress fracture.



▲ **Figure e4–3.** Fifth metatarsal fracture. (Used, with permission, from M. Dini, DPM.)

TREATMENT

There is controversy concerning the optimal treatment of fifth metatarsal fractures. *Blood supply plays an important role in the healing ability of fifth metatarsal fractures*. Perfusion to the fifth metatarsal comes from the metaphyseal arteries at the base of the metatarsal. A nutrient artery also enters at the proximal diaphysis and crosses the watershed area. The watershed area is at the metaphyseal-diaphyseal junction. Most fifth metatarsal fractures that occur outside of the watershed region tend to heal with immobilization or protected weight bearing.

Nondisplaced and minimally displaced distal fifth metatarsal fractures can be treated with weight-bearing immobilization (short leg cast versus boot) for 4–6 weeks.

Treatment for a nondisplaced zone 1 fracture consists of a stiff-soled shoe (post-op/fracture shoe) or weight-bearing immobilization (short leg cast versus boot) for 6–8 weeks. Small displaced symptomatic tuberosity fracture fragments may require excision. Larger displaced or intra-articular fractures > 30% of the articular surface or with an articular step-off of 2 mm can be considered for surgical fixation.

Treatment for an acute nondisplaced zone 2 fracture is non–weight-bearing immobilization for 6–8 weeks. Prolonged duration of immobilization up to 12 weeks may be required if tenderness persists. For higher-performance athletes or those in symptomatic fracture patterns with nonunion/sclerosis, surgical management should be considered. Early surgical fixation of acute Jones fractures may result in shorter times to union, lower incidence of refracture, and return to athletics compared with conservative treatment.

Treatment for zone 3 acute nondisplaced fractures is non–weight-bearing immobilization for 6–8 weeks. Prolonged duration of immobilization up to 12 weeks or more may be required if tenderness persists. For higher-performance athletes or in symptomatic fracture patterns with nonunion/sclerosis, surgical management can be considered.

WHEN TO REFER

- If there are radiographic findings of a fracture.
- Persistent lateral foot pain that is unresponsive to conservative treatment.

Morton Neuroma

Monara Dini
Charles B. Parks

e4-05

ESSENTIALS OF DIAGNOSIS

- Shooting pain, numbness, or tingling in the interspace between the third and fourth metatarsal heads.
- Cramping, burning, and feeling of walking on a stone or marble.
- Pain and paresthesias that may radiate to the toes.
- Symptoms are exacerbated by wearing shoes with a narrow toe box or high heels.
- Classic "Mulder click" elicited in the interspace.

GENERAL CONSIDERATIONS

Morton neuroma is a common podiatric condition affecting the forefoot. It affects 10 times as many women as men and is usually diagnosed between 40 and 60 years of age. It mainly affects the third interspace but can also occur in other interspaces.

Anatomically, a Morton neuroma is an enlargement of the third common digital branch of the medial plantar nerve. The third common digital nerve receives a communicating branch from the lateral plantar nerve that passes deep to the deep transverse metatarsal ligament in the third interspace. It is a *benign growth* from the fibrous coverings of the nerve.

Many etiologies have been proposed, including trauma, ischemia, overpronation, equinus, intermetatarsal bursitis, and nerve entrapment due to mechanical impingement by the deep transverse metatarsal ligament.

CLINICAL FINDINGS

A. Symptoms and Signs

The most common symptom is shooting pain with associated numbness or burning in the third interspace or the third and fourth toes that is worse with weight bearing. These symptoms are exacerbated by wearing tight shoes but often improve with massage and rest. Diagnosis is mainly based on clinical findings and should include attention to shoes, gait, and neurologic abnormalities. A **Mulder click** may be palpated with compression of the foot from medial to lateral with simultaneous dorsal to plantar pressure on the third interspace. The affected toes may also appear to spread apart, which is referred to as the **Sullivan sign**.

B. Imaging

Plain films may assist in ruling out other causes of forefoot pain such as arthritis, avascular necrosis, and fractures. MRI is not necessary for diagnosis but can be used to rule out soft tissue masses and visualize a neuroma. Ultrasound is less expensive and can be used as an adjunct diagnostic tool.

TREATMENT

A. Conservative

Initial nonsurgical treatment of a Morton neuroma consists of wearing shoes with a wider toe box and avoiding tight shoes or high heels that aggravate symptoms. Metatarsal pads, orthotics, oral medications, and local injections with a corticosteroid and local anesthetic or alcohol sclerosing agents are also used.

B. Surgical

When patients do not respond to conservative management, surgical excision or decompression of the neuroma is recommended. Nerve decompression entails releasing the deep transverse metatarsal ligament to allow more space for the nerve. If the nerve is resected, the most common postoperative complication is a **stump neuroma**. A stump neuroma may be more painful than the original condition.

WHEN TO REFER

- If the patient has not responded to conservative treatment and symptoms persist.
- If the diagnosis is uncertain or another source of forefoot pain is suspected.

Onychocryptosis (Ingrown Nail)

e4-06

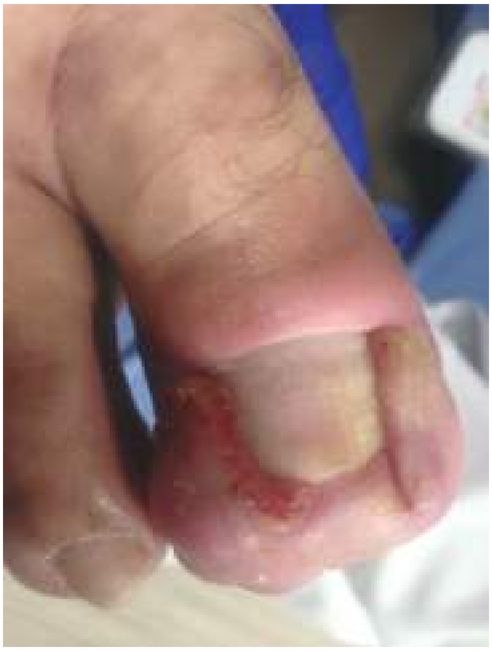
Monara Dini
Charles B. Parks

ESSENTIALS OF DIAGNOSIS

- Pain, erythema, and edema at the nail fold.
- Most commonly affects the great hallucal toenail.
- Chronic inflammation and infection can lead to formation of an abscess and hypergranulation tissue at nail folds.

GENERAL CONSIDERATIONS

Onychocryptosis is a common condition that occurs when the nail plate traumatizes periungual skin, which can cause inflammation that can eventually lead to infection (Figure e4–4). It commonly affects the hallux toenail but can also occur in the lesser digital nail plates. This disorder is more common in teenagers, with increasing prevalence throughout life. People who wear narrow shoes are at greater risk of developing an ingrown toenail.



▲ **Figure e4–4.** Ingrown toenail. (Used, with permission, from M. Dini, DPM.)

Ingrown toenails are caused by a combination of factors including improper nail care and hygiene, genetic predisposition, chronic trauma, aberrant nail anatomy, poorly fitting shoes, soft tissue abnormalities, and hyperhidrosis. *The most common cause is improper trimming that can lead to a spike of nail that anchors into the soft tissue*. This can cause local inflammation, formation of a granuloma, hypertrophy of the nail fold, and infection.

CLINICAL FINDINGS

Ingrown toenails can be classified into three stages: mild, moderate, and severe. In mild cases, there is pain with pressure, nail fold swelling, edema, and erythema. Moderate cases display increasing edema, erythema, warmth, seropurulent drainage, and ulceration of the nail fold. In severe cases, there is chronic inflammation and granulation tissue formation with associated nail fold hypertrophy.

TREATMENT

In general, an ingrown toenail is *not* a self-limiting problem and requires proper treatment for resolution.

A. Conservative

Nonsurgical intervention is most beneficial when the ingrown toenail is mild or moderate. This includes soaking the toe in warm water for 10–20 minutes, application of topical antibiotic ointment, or placing cotton wisps under the ingrown nail edge.

B. Surgical

Surgical interventions are more effective than conservative management in preventing the recurrence of an ingrown toenail. The most common surgical procedure to treat a locally infected ingrown toenail is a **partial nail avulsion** of the affected nail in conjunction with a

chemical matricectomy (the process of destroying all or part of the nail base or nail matrix) using 89% phenol or 10% sodium hydroxide. Other surgical procedures include radical excision of the nail fold, wedge resection, and total nail avulsion. Alternative methods include partial matricectomy using electrocautery, radiofrequency, and carbon dioxide laser ablation, but these are less common and more expensive.

COMPLICATIONS

Possible complications include regrowth of the nail spicule, infection, and damage to the nail matrix. There is *no* evidence supporting the use of antibiotics to prevent postoperative infections.

WHEN TO REFER

A referral to a podiatrist should be made to prevent spread of infection, especially in patients who are immunocompromised or have diabetes.

Achilles Tendonitis

Monara Dini
Charles B. Parks

e4-07

ESSENTIALS OF DIAGNOSIS

- Pain or swelling along the Achilles tendon.
- Pain with exercise.
- Pain when wearing shoes.

GENERAL CONSIDERATIONS

The Achilles tendon is the body's thickest and strongest tendon; it is composed of fibers of the gastrocnemius and soleus muscles. The tendon starts in the middle of the calf and internally rotates 90 degrees so that the soleus portion is medial distally. The tendon insertion is in the middle one-third of the posterior aspect of the calcaneus tuber.

The Achilles tendon does not have a synovial sheath that is typical for most tendons; however, it does have a **paratenon** that helps promote gliding during activity. The tendon remains mostly hypovascular, especially in the classic watershed area (3–6 cm proximal to insertion), but the paratenon is highly vascular.

The Achilles tendon, along with the gastrocnemius and soleus muscle complex, crosses three joints in the lower extremity. It participates in knee flexion, ankle flexion, and subtalar inversion. The tendon load has been reported to be as high as 12.5 times a person's body weight during running. This puts the tendon at risk for injury.

Achilles tendon pathology is often seen in both athletes and patients who are less active, with obesity being a major contributor. Achilles tendon conditions involve a combination of inflammation and degeneration, including insertional **Achilles tendinopathy, Achilles paratenonitis**, and **retrocalcaneal bursitis.**

CLINICAL FINDINGS

A. Symptoms and Signs

The pain from Achilles tendonitis usually begins with a mild aching sensation in the back of the heel or lower leg. Pain can be increased with exercise or certain activities, ie, climbing stairs or sprinting. An overuse injury can also precipitate symptoms, as can improper shoes.

B. Imaging

When insertional Achilles tendonitis is suspected, the lateral foot radiograph can show posterior bone spurs off the calcaneus or calcifications within the Achilles tendon (Figure e4–5). MRI and ultrasonography can provide more information regarding the level of disease within the substance of the tendon.

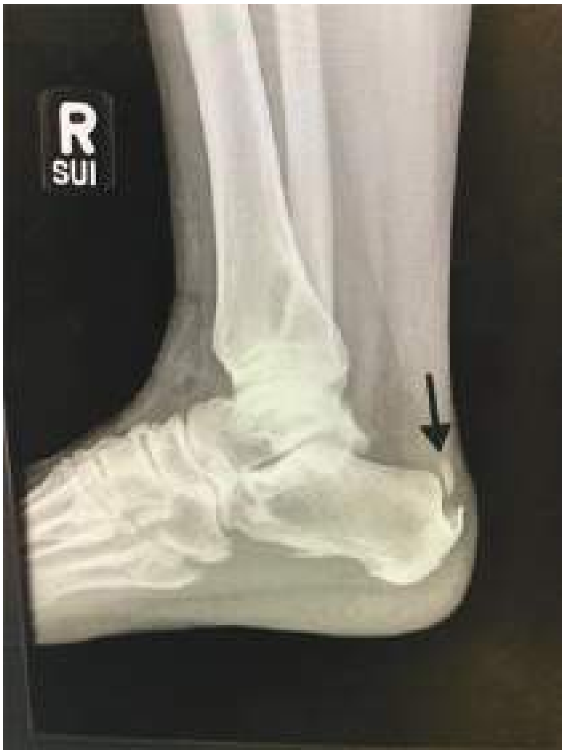

Figure e4–5. Achilles calcific tendonitis. (Used, with permission, from M. Dini, DPM.)

TREATMENT

A. Conservative

Initial conservative management should consist of NSAIDs, ice, rest, or activity modification. In combination with shoe modification, patients may benefit from an orthosis to help control hyperpronation, which often is a contributing factor. In patients with insertional Achilles tendinopathy, shoes that do not cause frictional pain are helpful in reducing symptoms. Physical therapy is beneficial, especially when strengthening, stretching, proprioception, and anti-inflammatory modalities are used in combination. Heel lifts help reduce the load on the Achilles during daily activity. Patients who do not respond well to these options or are nonadherent may benefit from immobilization in either a boot or a cast for a short period of time.

Injecting corticosteroids into the tendon is controversial because of the risk of rupture, especially without immobilization. Some studies suggest injecting platelet-rich plasma or sclerosing agents to help reduce pain and improve function, but supporting data are insufficient to support this therapy.

B. Surgical

Surgery for patients with insertional tendinopathy requires removal of the prominent bone, or the **Hagland deformity**, and debridement of the Achilles tendon. Often, this surgery involves removing a large part of the Achilles insertion to access the bony deformity or calcific tendinosis. The Achilles tendon then needs to be reattached.

When the insertion site is not the source of pain, tendon debridement can reduce symptoms. Other options include tendon transfers or augmentation, specifically with the flexor digitorum longus. Percutaneous options (Tenex and Topaz procedures) break up scar tissue and stimulate vasculature in order to reduce symptoms. Large studies have not been performed, however, to validate these treatment modalities.

WHEN TO REFER

- If the patient does not respond to shoe modification.
- If the patient has difficulty with daily activities or exercise regimen.

Plantar Fasciitis

Monara Dini
Charles B. Parks

e4-08

ESSENTIALS OF DIAGNOSIS

- Heel pain worse in the morning with initial weight bearing or after a period of rest.
- Heel pain precipitated by a recent increase in activity.
- Localized tenderness at the medial calcaneal tubercle.
- Pain with passive dorsiflexion of the great toe.

GENERAL CONSIDERATIONS

***Plantar fasciitis** is the most prevalent condition treated by podiatrists and is the most common cause of heel pain.* An estimated 2 million Americans are affected annually, resulting in > 1 million clinician visits. The estimated annual cost of treatment for plantar fasciitis is between $192 and $376 million.

The plantar fascia is a thick and fibrous aponeurosis that helps support the medial longitudinal arch of the foot through the windlass effect. It originates at the medial calcaneal tubercle and forms three bands: a thick central band and thinner medial and lateral bands. The plantar fascia divides distally into digital bands that insert onto the base of the proximal phalanx of each digit and metatarsal heads. Fibers from the plantar fascia also blend into the deep transverse metatarsal ligament and the flexor sheath.

Plantar fasciitis is believed to be caused by *repetitive microtrauma* and *biomechanical overuse*. Risk factors include pes planus as well as pes cavus foot types, obesity, limb length discrepancy, Achilles tendon tightness, and occupations that require prolonged standing or walking.

CLINICAL FINDINGS

A. Symptoms and Signs

The chief symptom is sharp and stabbing heel pain that is *most severe in the morning* (“first step of the day”) or *standing after rest*. The pain usually improves with ambulation but may worsen after activity or at the end of the day. On physical examination, there is localized tenderness upon palpation of the medial calcaneal tubercle. Passive dorsiflexion of the hallux may cause pain or discomfort in the plantar fascia. Evaluation of the ankle joint may reveal decreased dorsiflexion, indicating a tight Achilles tendon.

B. Imaging

Imaging is rarely needed since the diagnosis of plantar fasciitis is usually clinical. Imaging should be obtained if the diagnosis is uncertain or the patient has not responded to treatment. Weight-bearing anteroposterior, medial oblique, and lateral views of the foot can determine biomechanical etiologies of plantar fasciitis. An infracalcaneal heel spur seen on the radiograph may be associated with symptoms of plantar fasciitis and can indicate that the condition has occurred chronically. However, a heel spur does *not* necessarily correlate with symptoms and is found in asymptomatic individuals (15–25% of the general population); many patients with plantar fasciitis do not have heel spurs.

Changes in the consistency and thickness of the plantar fascia have been noted both on MRI and ultrasonography in patients with plantar fasciitis; however, these diagnostic tests should be reserved for confirmation of plantar fascia rupture.

DIFFERENTIAL DIAGNOSIS

A neurologic etiology of heel pain can be assessed by examining for paresthesias, Tinel sign, or motor weakness. Examination for traumatic causes of heel pain is performed by squeezing the calcaneus and inspection of the heel for trauma and wounds.

TREATMENT

A. Conservative

Initial treatment of plantar fasciitis consists of stretching the Achilles and plantar fascia, padding and strapping of the arch, supportive shoe gear, rest and avoidance of high-impact activities, orthotics, oral NSAIDs, night splints, and corticosteroid injections. Instructions to stretch the Achilles and plantar fascia are as follows: stand an arm’s length from a wall, place your right foot behind your left, slowly and gently bend your left leg forward, keep your right knee straight and your right heel on the ground, hold the stretch for 15 to 30 seconds and release, reverse the position of your legs, and repeat. Patients usually respond to treatment within 6 weeks; if the patient experiences improvement in symptoms, the treatment should be continued until resolution. Extracorporeal shock wave therapy, iontophoresis, botulinum toxin injections, and platelet-rich plasma injections have shown promising results but have not been supported with good-quality evidence. Limited evidence supports the conclusion that any of the newly mentioned modalities are superior to steroid injections or other conservative methods of treatment.

B. Surgical

Plantar fasciotomy done through either open or endoscopic technique may be effective for plantar fasciitis that does not respond to conservative treatment after 1 year.

WHEN TO REFER

- If the patient has not responded to conservative treatment within 6 weeks.
- If the diagnosis is uncertain or another source of heel pain is suspected.

Plantar Plate Injuries (Predislocation Syndrome)

e4-09

Monara Dini
Charles B. Parks

ESSENTIALS OF DIAGNOSIS

- Plantar forefoot pain, usually underneath the second toe.
- Deformity of toe, particularly the second.
- Lack of toe purchase (toe touching the ground).

GENERAL CONSIDERATIONS

The pain with a **plantar plate injury** is underneath the second toe and can either start suddenly with a sharp pain or can develop gradually over time. In either case, if it is not treated, the patient tends to suffer with constant pain under the ball of the foot.

The plantar plate is a supporting structure between the metatarsals and the remainder of the foot. The plantar plate, located at the level of the MTP joint, is made of fibrocartilage and fibrous slips. The plantar plate, as an extension of the plantar fascia, withstands compressive loads from the metatarsal. The plantar plate has attachments along the proximal phalanx, plantar fascia, and collateral ligaments. The plantar plate is weakest at the metatarsal neck due to the thin synovial attachment. The second metatarsal undergoes the most stress during weight bearing; therefore, the second plantar plate has a higher predisposition to injury.

CLINICAL FINDINGS

A. Symptoms and Signs

Patients usually have some pain localized to the affected plantar plate, most often the second. They can experience some edema or a sensation of something “bunched” up under the metatarsal head. In an acute rupture or with chronic symptoms, the toe can drift medially (more often) or laterally and develop into a hammertoe deformity. During this process, the toe may lack ground purchase.

B. Imaging

Radiographs of the foot are helpful in showing dorsal dislocation of the proximal phalanx at the level of the MTP joint. MRI is often indicated to help assess the extent of plantar plate attenuation and degeneration, especially if surgery is being considered. Arthrograms can be performed in conjunction with MRI.

TREATMENT

A. Conservative

If the deformity is mild, the toe can be taped or splinted down. Typically, Budin splints are used to hold the toe in proper alignment and allow purchase of the toe. Orthotics, both over-the-counter and custom-made, can also relieve pain by helping maintain more normal mechanics. If there is an *equinus component* (lack of dorsiflexion of the ankle due to tight gastrocnemius or soleus muscle) to the etiology of the plantar plate injury, Achilles stretching may also help alleviate pain. Immobilization can help in some patients with acute onset of symptoms.

B. Surgical

Many surgical techniques have been described for repair of lesser MTP joint instability with plantar plate involvement. Both dorsal and plantar approaches have been described to repair plantar plate injuries and tears. Concomitant PIP joint fusion and a Weil shortening osteotomy of the metatarsal have been performed. Plantar plate tears can be repaired primarily, or they can be anchored into the base of the proximal phalanx. These treatment options have shown improvements in patient function and pain and have ultimately improved the patient’s deformity.

WHEN TO REFER

- If patient is having forefoot pain in conjunction with lesser toe deformity.
- Difficulty with wearing shoes due to lesser toe deformity.

Flatfoot (Pes Planus)

Monara Dini
Charles B. Parks

e4-10

ESSENTIALS OF DIAGNOSIS

- May present with a wide array of symptoms, including muscle fatigue and pain in the arch, heel, lateral ankle, or along the course of the posterior tibial tendon.
- Inability to perform or pain upon performing a single-leg heel raise.
- Decreased medial longitudinal arch height.
- Difficulty in walking.
- Difficulty with shoe wear.

GENERAL CONSIDERATIONS

Flatfoot deformity is common, but most cases are asymptomatic. Flatfoot is also known as **adult-acquired flatfoot**, **pes planus**, or **pes planovalgus.** There is a wide range of presenting ages and complaints. Flatfoot is a progressive deformity characterized by the collapse of the medial longitudinal arch with forefoot abduction and hindfoot valgus (Figures e4–6 and e4–7). There are numerous causes of flatfoot including rearfoot equinus, tendon laceration, tarsal coalition, arthritis, neuroarthropathy, muscle imbalances, ligamentous laxity, and neurologic weakness. Most cases of flexible pes planus are associated with generalized ligamentous laxity.

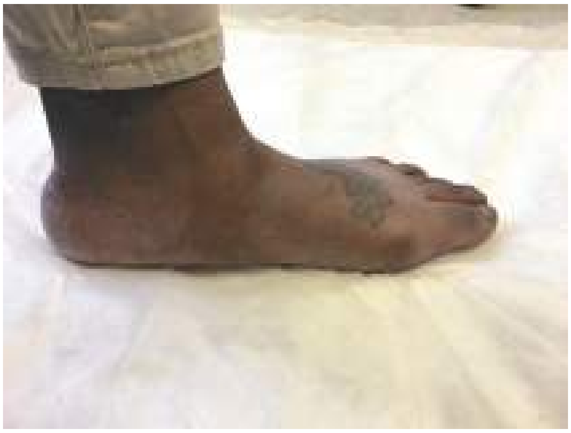
The most common etiology of flatfoot deformity is posterior tibial tendon dysfunction. Even with most causes associated with posterior tibial tendon dysfunction, it is still necessary to evaluate patients for other possible causes to ensure optimal treatment. Patients with congenital ligamentous laxity secondary to Down syndrome, Marfan syndrome, or Ehlers-Danlos syndrome are susceptible to developing flatfoot. Ligamentous laxity seen in pregnancy may also cause flatfoot, but this usually corrects itself soon after delivery. Patients with degenerative or inflammatory arthropathies, rheumatoid arthritis, or seronegative arthropathies are at higher risk for developing flatfoot. A common result in Charcot neuroarthropathy leads to midfoot collapse with a rigid rocker-bottom flatfoot.

Flatfoot is common in the first decade of life, when most infants are born with flatfeet and develop a medial arch during their first decade of life. Children and early adolescents are prone to flatfeet because of ligamentous laxity and lack of neuromuscular control. Most instances of flatfoot in children are flexible, meaning there is an arch present without weight bearing but collapses with weight bearing. Younger patients with rigid flatfoot should be screened for tarsal coalition, congenital vertical talus, accessory navicular, or other hindfoot pathologies. Studies support the theory that asymptomatic flatfoot can progress into symptomatic flatfoot over time as ongoing degenerative processes change flexible deformities into a rigid deformity.

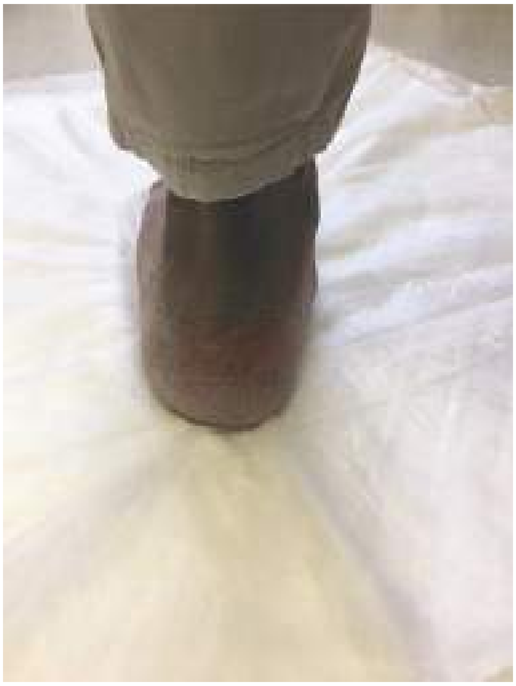
CLINICAL FINDINGS

A. Symptoms and Signs

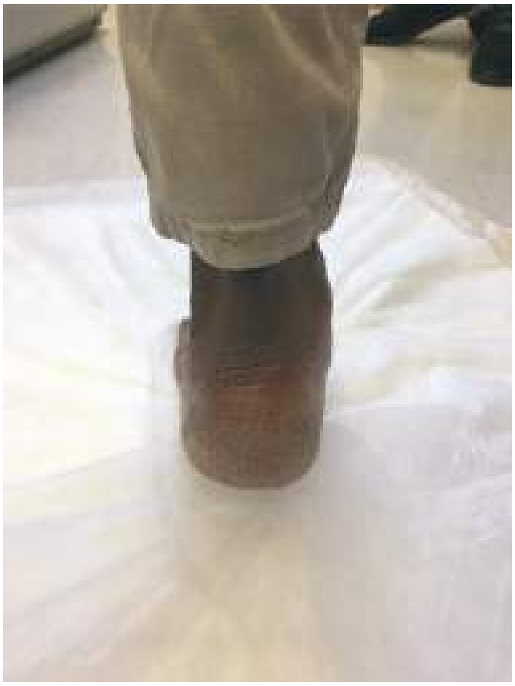
The flatfoot may or may not be symptomatic. Pain coincides variably with the severity or progression of the



▲ **Figure e4–6.** Weight-bearing examination of collapse of the medial longitudinal arch and the foot in a pronated position. (Used, with permission, from C. Parks, DPM.)



▲ **Figure e4–7.** "Too many toes" sign with the forefoot abduction where the lesser toes are visible laterally. Also seen is the hindfoot valgus deformity. (Used, with permission, from C. Parks, DPM.)



▲ **Figure e4–8.** Single heel raise examination with the heel raised off the weight-bearing surface. The patient may or may not be able to perform the single heel raise or will be in pain while performing the single heel raise. Also shown is the posterior tibial dysfunction with the heel not being in rectus or an inverted state. (Used, with permission, from C. Parks, DPM.)

deformity. Patients may report arch, medial ankle, heel, or pretibial pain. Patients may also report lateral ankle pain due to lateral impingement (sinus tarsi and fibular-calcaneal), which is seen over time as the deformity progresses. When symptoms are present, patients frequently report a dull achy pain at the medial arch or medial ankle. They also may describe a feeling of "muscle weakness" or fatigue with exercises or standing for long periods.

The clinical examination should include a generalized overview of the foot type, a gait analysis, and an examination of the foot and ankle in both weight-bearing and non–weight-bearing. There is a variable spectrum of presentation from flexible to rigid. Upon inspection, the foot may have an arch when non–weight-bearing but flattens with weight bearing. The arch may reconstitute with toe walking, hallux dorsiflexion at the first MTP joint (activation of the windlass mechanism), or hanging the foot in plantarflexion. Upon weight bearing and gait analysis, the medial longitudinal arch may collapse, the "too many toes" sign, valgus hindfoot deformity, and forefoot abduction. Examination should include an evaluation of the ankle joint and subtalar joint range of motion. In a flexible deformity, the examiner can passively correct the deformity to a plantigrade foot. In a rigid deformity, the examiner cannot correct the deformity. The heel cord can have a contracture (ankle joint equinus) with lateral deviation of the Achilles with weight bearing. Severe Achilles contracture is associated with midfoot breakdown.

If the patient reports pain in the medial ankle or pain during the examination posterior to the medial malleolus, posterior tibial tendon dysfunction should be strongly suspected. Examination should include a single heel raise, with the heel raising off the ground and inverting (Figure e4–8). If patients cannot perform the single heel raise or if there is pain with this motion, the posterior tibial tendon is weak and inflamed. The posterior tibial tendon's strength should be examined by manual muscle testing by positioning the foot in plantarflexion and full inversion. If the patient cannot maintain this foot position when the examiner applies an eversion force, the posterior tibial tendon is underpowered.

B. Imaging

Plain radiographs are used to determine the severity of a flatfoot deformity or to rule out other mimicking conditions. Weight-bearing anteroposterior, oblique, and lateral radiographs of the foot are the most useful images (Figure e4–9). On a weight-bearing anteroposterior view of the foot, the following will be evaluated: talar head coverage, increased talocalcaneal angle, cuboid-abduction angle, and talar-first metatarsal axis. The oblique view is to help rule out a tarsal coalition. Another view called the **Harris-Beath view** can help rule out a tarsal coalition. A weight-bearing lateral radiograph of the foot can evaluate for decreased calcaneal inclination angle, increased talar declination angle, increased first metatarsal declination

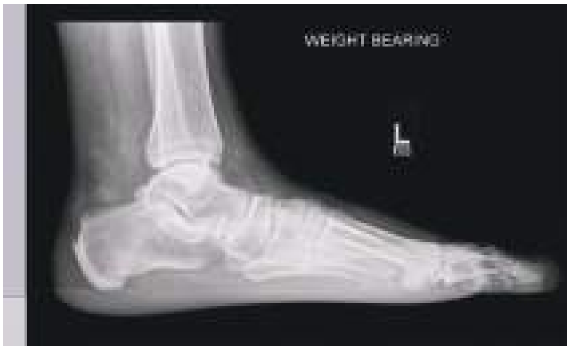


Figure e4–9. **A weight-bearing lateral radiograph of a foot. Visible here is a decreased calcaneal inclination angle, increased talar declination angle, increased first metatarsal declination angle, anterior break of the Cyma line, and incongruent Meary angle.** (Used, with permission, from C. Parks, DPM.)

angle, anterior break in the Cyma line, and the Meary angle.

MRI in later stages of this deformity may show a varying amount of posterior tibial tendon degeneration and arthritic changes in the talonavicular, subtalar, and tibiotalar joints.

STAGING

Since the severity of the deformity varies depending on the pathological anatomy and changes in biomechanics, staging can be helpful in guiding treatment protocols. *Johnson and Strom* (later modified by *Myerson*) is a widely used classification system that also gives recommendations on possible procedures to be performed according to the stage of the deformity. Johnson and Strom published their three stages in 1989, and Myerson added the fourth stage in 1996. It is very common to perform a combination of procedures because this is a complicated deformity with multiple planes of motion affected. The classification system focuses on deformity, flexibility or rigidity, and muscle strength and degeneration.

Stage I

Stage I includes tenosynovitis with mild tendon degeneration. Findings might include tenderness along the course of the posterior tibial tendon. The tendon strength may have a mild weakness, if any, assessed by the single heel raise. The foot usually demonstrates normal alignment with a flexible hindfoot. With gait analysis, there will be an absence of the “too many toes” sign.

Stage II

Stage II includes elongation of the posterior tibial tendon with tendon degeneration. The hindfoot deformity remains flexible. There is marked weakness and pain of the posterior tibial tendon with the single heel raise. There may be pain with palpation along the course of the posterior tibial tendon. In this stage, the disease is a dynamic deformity with hindfoot valgus and forefoot abduction. With gate analysis, a positive “too many toes” sign will be present (visualization of the lateral toes with gate analysis of the patient from behind).

Stage III

Stage III includes chronic dysfunction with elongated and possible rupture of the posterior tibial tendon. The lengthening of the posterior tibial tendon leads to a rigid hindfoot valgus deformity. Because of this rigid hindfoot valgus deformity, the forefoot usually compensates with a supination. There is marked weakness and pain with single heel raise test or inability to perform the test. Also, the “too many toes” sign is seen with gait analysis. There can be lateral ankle pain due to lateral impingement (sinus tarsi and fibular-calcaneal impingement).

Stage IV

Stage IV includes the same findings of stage III but with ankle joint valgus. Longstanding hindfoot valgus places increasing stress on the deltoid complex with eventual failure, which results in a valgus tilt of the talus. This change in the biomechanical forces of the ankle joint results in arthrosis of the joint.

TREATMENT

A. Conservative

Conservative care entails patient education of the natural history of the deformity and biomechanical support, which is appropriate for some flexible and asymptomatic patients. Also, conservative treatment is indicated for patients who are not candidates for or not amenable to surgical intervention. Stretching, muscle strengthening, shoe gear modifications, and orthotics are all types of conservative treatments. A supportive “motion control” type of shoe is recommended. Functional orthotics include a custom or prefabricated orthotic device, which can aid in providing arch support, changing the heel strike position, and heel support during the gait cycle. Orthotics may help the patient’s discomfort but will not change the natural progression of the deformity or reverse the flatfoot deformity. Anti-inflammatory medications, such as NSAIDs, may provide symptomatic relief.

B. Surgical

Pain, discomfort, and rigid deformity are the major considerations for surgical correction. Many different surgical treatments have been described in the literature to correct flatfoot deformities, and because this deformity affects multiple joints and planes of motion, a combination of procedures are typically performed together. Because it is a disorder with a spectrum of deformities, there is controversy over surgical options throughout the stages of the deformity. Surgical options may include procedures of tendon debridement, tendon balancing (including lengthening or transfer), osteotomy, or arthrodesis.

WHEN TO REFER

- If the patient has not responded to conservative treatment.
- There is severe deformity or fixed deformity.
- There is severe pain or posterior tibial tendon weakness.
- There is difficulty with ambulation or footwear problems.

Callosities & Corns of Feet or Toes

e4-11

Monara Dini
Charles B. Parks

Callosities and **corns** are caused by pressure and friction due to faulty weight bearing, orthopedic deformities, improperly fitting shoes, or neuropathies.

Tenderness on pressure and "after-pain" are the only symptoms. The hyperkeratotic well-localized overgrowths *always occur at pressure points.* Dermatoglyphics (fingerprint lines) are preserved over the surface (not so in warts). When the surface is shaved with a 15-blade, a glassy core is found (differentiating them from plantar warts, which have multiple capillary bleeding points or black dots when pared).

Treatment consists of correcting mechanical abnormalities that cause friction and pressure. Callosities may be removed by careful paring of the callus after a warm water soak or with keratolytic agents as found in various brands of corn pads.

Plantar hyperkeratosis of the heels can be treated successfully by using 20% urea (Ureacin 20) or 12% lactic acid (Amlactin) or combinations nightly and a pumice stone after soaking in water.

Callosities on diabetic feet, especially in the setting of hyposensate neuropathy, can be a major problem and the value of early podiatric management to prevent complications is very high.

Part e5: Appendix: Therapeutic Drug Monitoring, Pharmacogenetic Tests, Laboratory Reference Intervals, & Commonly Used Blood Specimen Collection Tubes

e5-01

Therapeutic Drug Monitoring

Chuanyi Mark Lu

Table e5–1. Therapeutic drug monitoring.[1] Reproduced with permission from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustments	Comments
Amikacin	**Conventional dosing:** Peak: 20–30 mg/L; trough: < 8 mg/L **High dose once daily:** Peak: 60 mg/L; trough: < 5 mg/L	2–3; ↑ in uremia	↓ in kidney dysfunction	Concomitant kanamycin or tobramycin therapy may give falsely elevated amikacin results by immunoassay. The dosing interval should be adjusted based on renal function.
Amitriptyline	95–250 ng/mL **Panic:** ≥ 500 ng/mL	9–25	No dosage adjustments provided in manufacturer's labeling	Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration. Use with caution in patients with kidney or liver dysfunction. To avoid side effects, start with a low dose and then slowly increase the dose.
Carbamazepine	4–12 mg/L	10–15	↓ (75% of dose) in severe kidney dysfunction; use with caution in liver dysfunction	Induces its own metabolism, primarily in the liver. Metabolite 10,11-epoxide exhibits 13% cross-reactivity by immunoassay. Adverse reactions: skin reactions, myelosuppression. Patients with HLA-B*1502 should avoid carbamazepine. Consider measuring blood 10,11-carbamazepine epoxide level when toxicity is suspected, but carbamazepine level is within normal range.

(*continued*)

Source: Chapter adapted and updated, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.

Table e5–1. Therapeutic drug monitoring.[1] Reproduced with permission from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017. (continued)

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustments	Comments
Cyclosporine	100–300 mcg/L (ng/mL) whole blood, 12-hour trough. Target concentrations vary depending upon disease being treated.	6–12	↓ in kidney or liver dysfunction	Cyclosporine is lipid-soluble (20% bound to leukocytes; 40% to erythrocytes; 40% in plasma, highly bound to lipoproteins); the binding is temperature-dependent in vitro and concentration-dependent in vivo. HPLC and LC-tandem mass spectrometry methods are highly specific for parent drug and considered as the gold standard assays. Monoclonal fluorescence polarization immunoassay (FPIA) and monoclonal chemiluminescence immunoassay also measure cyclosporine reliably; polyclonal immunoassays are less specific due to cross-reaction with drug metabolites. Anticonvulsants and rifampin increase its metabolism. Erythromycin, ketoconazole, and calcium channel blockers decrease its metabolism. The main adverse reaction is concentration-related nephrotoxicity.
Desipramine	100–250 ng/mL **Panic:** ≥ 500 ng/mL	13–23	No dosage adjustments provided in manufacturer's labeling	Is an active metabolite of imipramine. Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration. To avoid side effects, start with a low dose and then slowly increase the dose.
Digoxin	HF: 0.5–0.9 mcg/L Atrial fibrillation: 0.5–2 mcg/L	36–42; ↑ in uremia, HF	↓ in kidney dysfunction, HF, hypothyroidism; ↑ in hyperthyroidism	Bioavailability of digoxin tablets is 50–90%. Specimen must not be drawn within 4 hours of an intravenous dose or 6 hours of an oral dose. Dialysis does not remove a significant amount. Hypokalemia potentiates toxicity. Digitalis toxicity is a clinical and *not* a laboratory diagnosis. Digibind (digoxin-specific antibody) therapy of digoxin overdose can interfere with measurement of digoxin levels depending on the digoxin assay. Elimination reduced by amiodarone, quinidine, and verapamil.
Ethosuximide	40–100 mg/L	Child: 30–40 Adult: 50–60	No dosage adjustments provided in manufacturer's labeling	Levels used primarily to assess clinical response and compliance. Toxicity is rare and does not correlate well with plasma concentrations. Use with extreme caution in patients with kidney or liver dysfunction.

(continued)

Table e5–1. Therapeutic drug monitoring.[1] Reproduced with permission from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017. (continued)

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustments	Comments
Gentamicin	**Conventional dosing:** Peak: 4–8 mg/L; trough: < 2 mg/L **High dose once daily:** Peak: 20 mg/L; trough: undetectable	2–3; ↑ in uremia (7.3 during dialysis)	↓ in kidney dysfunction	Draw peak specimen (conventional dosing) 30 minutes after end of 30- to 60-min infusion. Draw trough just before next dose. The dosing interval should be adjusted based on renal function. In uremic patients, some penicillins (eg, carbenicillin, ticarcillin, piperacillin) may decrease gentamicin half-life from 46 hours to 22 hours, posing a risk of reduced antibacterial efficacy. The main adverse reactions are CNS, otic, and kidney toxicities.
Imipramine	180–350 ng/mL **Panic:** ≥ 500 ng/mL	10–16	No dosage adjustments provided in manufacturer's labeling	Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration. To avoid side effects, start with a low dose and then slowly increase the dose.
Lidocaine	1–5 mg/L **Panic:** ≥ 7.0 mg/L	1–2; ↔ in uremia, HF; ↑ in cirrhosis	↓ in HF, liver dysfunction	Levels increased with cimetidine therapy. CNS toxicity common in older adults.
Lithium	0.5–1.2 mmol/L	10–35; ↑ in uremia	↓ in kidney dysfunction	Thiazides and loop diuretics may increase serum lithium levels.
Methotrexate	< 1.0 mcmol/L 48 hours post high-dose therapy, or according to protocol	3–10 low dose; 8–15 high dose; ↑ in uremia	↓ in kidney dysfunction	Therapeutic concentrations depend on the treatment protocol (low versus high dose) and time of specimen collection. 7-Hydroxymethotrexate cross-reacts 1.5% in immunoassay. To minimize toxicity, leucovorin (also known as folinic acid, which "rescues" normal cells) should be given parenterally if methotrexate level is > 0.1 mcmol/L at 48 hours after start of therapy. Methotrexate level > 1 mcmol/L at > 48 hours requires an increase in dose of such "rescue" therapy. In patients with methotrexate level > 1 mcmol/L and impaired kidney function, glucarpidase (an enzyme that inactivates methotrexate, given by intravenous injection) can be used instead as the "rescue." However, rebound of methotrexate concentration may occur 48 hours after glucarpidase "rescue."

(*continued*)

Table e5–1. Therapeutic drug monitoring.[1] Reproduced with permission from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017. (continued)

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustments	Comments
Nortriptyline	50–150 ng/mL **Panic:** ≥ 500 ng/mL	18–44	↓ in liver dysfunction	Is an active metabolite of amitriptyline. Drug is highly protein-bound. Patient-specific decrease in protein binding may invalidate quoted therapeutic reference interval for effective concentration. To avoid side effects, start with a low dose and then slowly increase the dose.
Phenobarbital	10–40 mg/L	Child: 37–73 Adult: 53–140; ↑ in cirrhosis	↓ in liver dysfunction	Metabolized primarily by the hepatic microsomal enzyme system. Many drug–drug interactions.
Phenytoin	10–20 mg/L; 5–10 mg/L in uremia and severe hypoalbuminemia **Panic:** ≥ 35 mg/L	Dose/concentration-dependent	No dosage adjustments provided in manufacturer's labeling	Drug metabolite cross-reacts in immunoassays; the cross-reactivity may be of significance only in the presence of advanced chronic kidney disease. Metabolism is capacity-limited. Increase dose cautiously when level approaches therapeutic reference interval since new steady-state level may be disproportionately higher. Drug is very highly protein-bound; protein binding is decreased in uremia and hypoalbuminemia. Monitoring free (unbound) drug level (pharmacologically active fraction, target range 0.5–2.0 mg/L) is recommended in severe kidney and liver dysfunction.
Sirolimus	Trough: 4–12 ng/mL when used in combination with cyclosporine A; 12–20 ng/mL if used alone. Target trough concentrations vary based on clinical context and use of additional immunosuppressants.	57–63	↓ in liver dysfunction and with drugs inhibiting CYP3A4 activity. No dosage adjustment is necessary for kidney impairment.	Sirolimus is an immunosuppressant used in combination with cyclosporine and corticosteroids for prophylaxis of organ rejection after kidney transplantation. It has also been used in liver and heart transplantation. When used in combination with cyclosporine, careful monitoring of kidney function is required. Once the initial dose titration is complete, monitoring sirolimus trough concentrations weekly for the first month and every 2 weeks for the second month appears to be appropriate. The optimal time for specimen collection is 24 hours after the previous dose or 0.5 to 1 hours prior to the next dose (trough level).

(*continued*)

Table e5–1. Therapeutic drug monitoring.[1] Reproduced with permission from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017. (continued)

Drug	Effective Concentrations	Half-Life (hours)	Dosage Adjustments	Comments
Tacrolimus	Trough: 8–12 ng/mL whole blood, 12- or 24-hour trough for immediate- or extended-release preparations, respectively. Target concentrations vary depending upon disease being treated.	8.7–11.3	↓ in liver dysfunction and with drugs inhibiting CYP3A4 activity; ↑ starting dose to 1.5–2× usual dose for rapid and intermediate CYP3A5 metabolizers.	Tacrolimus is used for prophylaxis of organ rejection in adult patients undergoing liver or kidney transplantation and in pediatric patients undergoing liver transplantation. It has also been used to prevent rejection in heart, small bowel, and allogeneic stem cell transplantation patients and to treat autoimmune diseases. Antacid or sucralfate administration should be separated from tacrolimus by at least 2 hours. The optimal time for specimen collection is 12 hours (immediate-release) or 24 hours (extended-release) after the previous dose or 0.5 to 1 hours prior to the next dose (trough level).
Theophylline	5–15 mg/L **Panic:** ≥ 30 mg/L	4–9	↓ in HF, cirrhosis, and with cimetidine	Caffeine cross-reacts 10%. Elimination is increased 1.5–2× in smokers. 1,3-Dimethyl uric acid metabolite increased in uremia and, because of cross-reactivity, may cause an apparent slight increase in serum theophylline.
Tobramycin	**Conventional dosing:** Peak: 5–10 mg/L; trough: < 2 mg/L **High dose once daily:** Peak: 20 mg/L; trough: undetectable	2–3; ↑ in uremia	↓ in kidney dysfunction	The dosing interval should be adjusted based on renal function. Tobramycin, kanamycin, and amikacin may cross-react in immunoassay. Some antibiotics may decrease tobramycin half-life in patients with uremia, causing reduced antibacterial efficacy.
Valproic acid (Valproate), total	50–100 mg/L; 50–125 mg/L for bipolar disorder **Panic:** > 150 mg/L	Child: 6–8 Adult: 10–12	Contraindicated in severe liver dysfunction	Significant fraction of the drug is protein-bound in vivo (concentration-dependent). Decreased binding in severe kidney disease and in liver dysfunction. Monitoring only total drug levels may be misleading. Monitoring with both total and free drug levels is preferred. Plasma concentrations show poor correlation with effect.
Vancomycin	Trough: 10–20 mg/L **Panic:** ≥ 35 mg/L	4–7; ↑ in severe kidney dysfunction	↓ in kidney dysfunction	Trough concentrations are recommended for monitoring vancomycin efficacy. Ototoxicity in uremic patients may lead to irreversible deafness. Monitoring serum levels to prevent ototoxicity in patients with normal kidney function receiving vancomycin monotherapy is not effective since this toxicity is rarely associated with monotherapy and does not correlate with serum levels. Data do not support using peak levels to monitor nephrotoxicity. Use trough levels.

[1] Serum from a plain red-top tube is typically used for therapeutic drug monitoring except for cyclosporine and tacrolimus, which require whole blood sample in a lavender (EDTA) tube. In general, the specimen should be drawn just before the next dose (trough).

↑, increased; ↓, decreased; ↔, unchanged; CYP, cytochrome P450; HF, heart failure; HPLC, high-performance liquid chromatography; LC, liquid chromatography.

e5-02

Selected Pharmacogenetic Tests: Clinical Relevance

Chuanyi Mark Lu

Source: Chapter adapted and updated, with permission, from Nicoll D et al. *Guide to Diagnostic Tests*, 7th ed. McGraw-Hill, 2017.

Table e5–2. Selected pharmacogenetic tests: clinical relevance[1] (listed in alphabetical order, within categories).

Pharmacogenetic Biomarker	Selected Variants (variant allele, activity)	Allele Frequency	Drugs	Clinical Relevance
Inherited Variants				
Apolipoprotein E (APOE)	_APOE ε2_ (_APOE2_) _APOE ε3_ (_APOE3_) _APOE ε4_ (_APOE4_)	_APOE2_, _APOE3_, and _APOE4_ are present in 8–12%, 75–80%, and 10–15% of general population, respectively. Homozygous _APOE4_ is seen in about 2–3% of population.	Lecanemab	_APOE_ genotyping is recommended for all treatment candidates before initiating lecanemab therapy to inform the risk of developing amyloid-related imaging abnormalities (ARIA). _APOE4_ carriers (especially ε4/ε4 homozygotes) are at significantly increased risk for ARIA, including symptomatic, serious, and severe ARIA (eg, cerebral hemorrhages).
CF transmembrane conductance regulator (CFTR)	_CFTR G551D_ (defective)	Present in about 4% of patients with CF.	Ivacaftor	CFTR protein forms a channel that allows chloride ions to cross the membrane. In patients with CF and the pathogenic CFTR G551D variant, the channel fails to open. Ivacaftor corrects the effects of this variant and is approved for persons with CF age > 6 years who have at least one copy of the G551D variant.
CYP2C19 variants	_2C19*2_ (681G>A, none); _2C19*3_ (636G>A, none); _2C19*4_ (1A>G, none); _2C19*5_ (1297C>T, none); _2C19*17_ (g.-3402C>T and g.-806C>T, ↑)	Nonfunctional variants are present in 12–25% of Asian individuals, and 2–7% of White and Black individuals; 2C19*17 carrier status is present in about 25% of White individuals.	Clopidogrel	Clopidogrel must be metabolized in the liver by CYP isoenzymes, principally CYP2C19, to become active. When treated with clopidogrel at recommended dosages, patients with nonfunctional CYP2C19 variants have more cardiovascular events than do patients with normal CYP2C19 function. Alternative drug or intervention strategies should be considered for patients with 2C19 variants. The novel CYP2C19*17 carrier status is associated with increased enzyme activity and an increased risk of bleeding. _CYP2C19_ genotyping is recommended for patients who have had a cardiovascular event while taking clopidogrel or patients who are at high risk for poor outcomes.
CYP2D6 variants	_2D6*1_ (fully functional "wild-type"); _2D6*2_ (2850C>T or 4180G>C; normal function variant); _2D6*3_ (2549delA with or without 1749A>G), 2D6*4 (1846G>A, with or without 1858C>T, 2938C>T or 3877G>C), 2D6*5 (whole gene deletion) and 2D6*6 (1707delT) (nonfunctioning variants); _2D6*9_ (1615-2617delAAG), 2D6*10 (100C>T), and 2D6*17 (1023C>T, 2850C>T) (partially functioning variants)	1–2% of the general population carry > two copies of functional alleles (eg, *1/*1×N or *1/*2×N) and phenotypically ultra rapidly metabolize. 5–10% of the general population carry no functional alleles (eg, *4/*4, *4/*5, *5/*5, or *4/*6) and phenotypically poorly metabolize.	Codeine, nortriptyline	Both codeine and nortriptyline are metabolized in the liver by CYP2D6. Codeine is a prodrug and needs to be metabolized by CYP2D6, primarily to morphine, whereas nortriptyline is the active moiety and its metabolism results in inactivation of the drug. At conventional doses, patients who poorly metabolize codeine based upon _CYP2D6_ genotype will derive no therapeutic benefit from codeine but may be "overdosed" with nortriptyline and are at increased risk for adverse effects. Conversely, at conventional doses of codeine, patients who rapidly metabolize codeine have higher than expected morphine levels (an initial "overdose"), with more adverse effects and a shorter than expected duration of pain control. On the other hand, patients may derive no therapeutic benefit from nortriptyline because of excessive metabolism of the drug.

(_continued_)

Table e5–2. Selected pharmacogenetic tests: clinical relevance[1] (listed in alphabetical order, within categories). (continued)

Pharmacogenetic Biomarker	Selected Variants (variant allele, activity)	Allele Frequency	Drugs	Clinical Relevance
CYP3A5 variants	3A5*1 (functional allele); 3A5*3 (6986A>G) (nonfunctional allele); 3A5*6 (14690G>A) and 3A5*7 (27131-27132ins T) (nonfunctional alleles)	3A5*3 is present in 82–95% of White individuals, 33% of Black individuals, and 65–85% of Asian individuals; 3A5*6 is present in 7–17% of Black individuals and 3A5*7 is present in 8% of Black individuals.	Tacrolimus	Tacrolimus is an immunosuppressant drug used after solid organ and hematopoietic stem cell transplantation. Individuals carrying two functional *1 alleles (*1/*1) rapidly metabolize tacrolimus. Individuals carrying one *1 allele and one nonfunctional allele (eg, *1/*3, *1/*6, *1/*7) metabolize at an intermediate rate. Individual carrying two nonfunctional alleles (*3/*3, etc.) *poorly* metabolize the drug. Individuals carrying one or two functional alleles have decreased dose-adjusted trough levels of tacrolimus compared with those who carry only nonfunctional alleles. Accordingly, an increase of standard starting dose of 1.5–2× usual dose is needed for those who intermediately or rapidly metabolize tacrolimus.
Dihydropyrimidine dehydrogenase (DPD) variants	*DPYD**2A (1905+1G>A, none); *DPYD**13 (1679T>G, ↓↓); *DPYD* rs67376798 (2846A>T, ↓↓)	Nonfunctional variants are present in 0.1–1% of White individuals (eg, French descent).	5-Fluorouracil, capecitabine	Fluoropyrimidines (ie, 5-fluorouracil, capecitabine) are metabolized by the DPD enzyme, encoded by the *DPYD* gene. To avoid severe or even fatal drug toxicity, an alternative drug should be selected for patients who are homozygous for *DPYD* nonfunctional variants (*2A, *13, or rs67376798). Consider a 50% reduction in starting dose for heterozygous patients who have low DPD activity (30–70% of normal).
Glucose-6 phosphate dehydrogenase (*G6PD*) gene	*G6PD A* (p.Asn126Asp and p.Val68Met): ↓enzyme activity; *G6PD Mediterranean* (p.Ser218Phe): ↓↓ enzyme activity; *G6PD Canton* (p.Arg489Leu): ↓↓ enzyme activity	5% prevalence worldwide (> 25% in countries where malaria is or was endemic). *G6PD A*, *G6PD Mediterranean*, and *G6PD Canton* are most common in Black individuals, White individuals, and Asian individuals, respectively. Approximately 400 million people worldwide have G6PD deficiency.	Rasburicase, tafenoquine	RBCs that lack the enzyme G6PD are sensitive to oxidative damage due to a deficiency in NADPH. Those who have G6PD deficiency are at risk for life-threating hemolytic reactions and methemoglobinemia if given oxidizing drugs such as rasburicase, a uric oxidase used to treat high levels of uric acid. Rasburicase is contraindicated for individuals who are G6PD deficient (with or without hemolytic anemia); an alternative drug (eg, allopurinol) should be used. Similarly, G6PD testing must be performed before prescribing the anti-malaria drug tafenoquine.
HLA-B*1502 allele	*HLA-B*1502*	Present in 5–15% of Asian individuals and 1–2% of White individuals.	Carbamazepine	Carbamazepine is associated with serious or even fatal adverse skin reactions, eg, Stevens-Johnson syndrome and toxic epidermal necrolysis. The reactions are significantly more common in patients who carry the *HLA-B*1502* allele. This allele occurs almost exclusively in patients with ancestry across broad areas of Asia, including Southeast Asia and India. *HLA-B*1502* genotyping may be useful for risk stratification in patients of Asian descent. Patients carrying the *HLA-B*1502* allele should not be given carbamazepine or oxcarbazepine unless the expected benefit clearly outweighs the increased risk of serious skin reactions. Testing for *HLA-A*3101* before carbamazepine treatment has also been recommended.

HLA-A*02:01 allele	*HLA-A*02:01*	Present in 27.1% of individuals of European descent, 11.9% of Black Americans, 6.5% Asian or Pacific Islanders, 17.4% Middle Eastern and Northern African individuals, 19.9% Hispanic individuals, and 19.4% American Indian.	Tebentafusp	Tebentafusp is an immunotherapy drug, approved for patients with HLA-A*02:01-positive uveal melanoma that is unresectable or metastatic. It is a bispecific fusion protein that binds to both melanoma cells (via HLA-A*02:01-glycoprotein 100) and T cells, facilitating tumor killing by T cells.
HLA-B*5701 allele	*HLA-B*5701*	Present in 6–8% of White individuals and selected Asian Indian individuals; present in 1–2% of Black and Asian individuals.	Abacavir	Abacavir is a nucleoside analog reverse transcriptase inhibitor used for HIV treatment. The major treatment-limiting toxicity for abacavir is drug hypersensitivity, occurring in 5–8% of recipients within 6 weeks of commencing therapy. There is an established association between carriage of the *HLA-B*5701* allele and abacavir hypersensitivity reactions. Patients who have the *HLA-B*5701* allele should not be prescribed abacavir or an abacavir-containing regimen.
HLA-B*5801 allele	*HLA-B*5801*	Present in 6–8% of Southeast Asian individuals and < 1% in White Western European individuals.	Allopurinol	Allopurinol can produce rare but severe hypersensitivity reactions (eg, toxic epidermal necrolysis and Stevens-Johnson syndrome), which are strongly associated with *HLA-B*5801* alleles. Patients of Korean, Han Chinese, Japanese, or Thai origin should be screened for *HLA-B*5801* allele, and if present, an alternative drug therapy is needed.
N-acetyltransferase 2 (*NAT2*)	*NAT2*5* (c.341T>C, ↓ activity); *NAT2*6* (c.590G>A, ↓ activity); *NAT2*7* (c.857G>A, ↓ activity); *NAT2*10* (c.499G>A, ↓ activity); *NAT2*14* (c.191G>A, ↓ activity); *NAT2*17* (c.434A>C, ↓ activity); *NAT2*19* (c.190C>T, ↓ activity) (*NAT2*4* is the wild-type reference)	*NAT2* alleles with decreased acetylation activity (*NAT2*5*, *6*, *7*, and *14*) are common in White persons, populations of African descent and Latino/Latina persons (25–45%), and relatively less common in Asian persons.	Amifampridine	The *NAT2* gene is highly polymorphic. Amifampridine is metabolized by NAT2 enzyme to inactive 3-N-acetyl-amifampridine. Individuals who metabolize the drug poorly have higher systemic drug concentrations, should use lowest recommended starting dosage, and should be closely monitored for adverse reactions. The NAT2 enzyme is also responsible for metabolizing several other drugs (eg, isoniazid).
Solute carrier organic anion transporter family member 1B1 (*SLCO1B1*) gene	*SLCO1B1*5* (c.521T>C, ↓ for TC-allele and ↓↓ for CC-allele)	20–30% of the general population are heterozygous (TC-allele, moderate risk) and 2–4% are homozygous (CC-allele, high risk) for the c.521T>C variant.	Simvastatin	SLCO1B1 is an influx transporter that moves drugs into hepatocytes. Decrease in the activity of this transporter (SLCO1B1 c.521T>C variant) is associated with increased blood drug levels and increased risk of statin-induced myopathy and statin intolerance. Genotyping is recommended for patients beginning statins, especially simvastatin.

(*continued*)

Table e5–2. Selected pharmacogenetic tests: clinical relevance[1] (listed in alphabetical order, within categories). (continued)

Pharmacogenetic Biomarker	Selected Variants (variant allele, activity)	Allele Frequency	Drugs	Clinical Relevance
Thiopurine methyltransferase (TPMT) variants	_TPMT*2_ (238G>C, ↓); _TPMT*3A_ (460G>A and 719A>G, ↓↓); _TPMT*3B_ (460G>A, ↓); _TPMT*3C_ (719A>G, ↓)	About 10–12% of White and Black individuals have reduced enzyme activity because they are heterozygous for one of the variant alleles. About 1 in 300 White individuals is homozygous for a variant allele.	AZA, 6-MP	AZA is a prodrug that is metabolized to 6-MP, which is then further metabolized to active 6-TG and inactive 6-MMP through hypoxanthine phosphoribosyltransferase and _TPMT_, respectively. Variation in the _TPMT_ gene can result in functional inactivation of the enzyme and an increased risk of life-threatening, 6-TG-associated myelosuppression. TPMT genotyping before instituting AZA or 6-MP can help prevent toxicity by identifying individuals with low or absent TPMT enzyme activity. Patients with homozygous or compound heterozygous variant alleles should not be given AZA or 6-MP (or start with a 90% dose reduction), while patients who are heterozygote with a single variant allele should be treated with lower doses. A similar strategy applies to loss-of-function variants in nudix hydrolase 15 (_NUDT15_) (eg, NUDT15*2 or *3). _NUDT15_ encodes enzymes that are also involved in the metabolism of AZA and 6-MP.
Uridine diphosphoglucuronosyltransferase 1A1 (UGT1A1) variants	_UGT1A1_*28 (7 TA repeats in promoter, ↓)	Homozygosity is present in 9–23% of White, Black, and South Asian Indian individuals, and in 1–2% of Eastern Asian individuals.	Irinotecan	Irinotecan is used in the treatment of metastatic CRC. Irinotecan is metabolized to active SN-38, a topoisomerase I inhibitor. SN-38 is further glucuronidated to inactive SN-38G by UGT1A1 and excreted. Heterozygous and homozygous UGT1A1*28 genotypes show a 25% and 70% decrease in enzyme activity, respectively. The presence of the UGT1A1*28 allele is a risk factor for the development of adverse reactions (eg, neutropenia, severe diarrhea). Testing for the allele can prevent drug toxicity at high doses of irinotecan.
Vitamin K epoxide reductase complex (VKORC1) variants	_VKORC1_ (–1639G>A)	The homozygous (–1639G>A) allele (–1639AA genotype) is present in approximately 15% of White and 80% of Chinese individuals.	Warfarin	The primary therapeutic target of warfarin is VKOR. Polymorphisms in the VKOR-encoding gene (_VKORC1_) explain about 30% of the phenotypic variability in drug effect. Patients carrying certain single nucleotide polymorphisms in the _VKORC1_ gene (especially the –1639G>A allele) require a lower warfarin maintenance dose to reach a therapeutic INR.
Somatic (acquired) Variants and Markers				
BRAF gene	_BRAF_ V600E or V600K pathogenic variant	40–60% of advanced melanomas; nearly all hairy cell leukemia.	Vemurafenib, encorafenib, dabrafenib, binimetinib, cobimetinib	Activating variants in BRAF (a serine–threonine protein kinase) are present in 40–60% of advanced melanomas. Most (80–90%) variants are the substitution of glutamic acid for valine at amino acid 600 (V600E variant). These variants are associated with a more aggressive clinical course. A BRAF inhibitor (eg, vemurafenib) has a high level of therapeutic activity against advanced melanomas containing the V600E/K variant as well as relapsed or refractory hairy cell leukemia.
Claudin 18.2	Claudin 18.2 protein expression as determined by qualitative IHC	44–47% of gastric and GEJ cancers are positive for claudin 18.2, using a ≥ 75% positivity cutoff to define a positive result.	Zolbetuximab	Claudin-18 is a protein that is encoded by the _CLDN18_ gene and belongs to the claudin family of proteins, which form tight junction strands in epithelial cells. Isoform 2 (Claudin 18.2) is normally expressed in gastric epithelium. Zolbetuximab is approved for the treatment of locally advanced, unresectable, or metastatic gastric or GEJ adenocarcinoma that is HER2-negative and positive for Claudin 18.2, the therapeutic target.

Epidermal growth factor receptor (EGFR) (also known as human epidermal growth factor receptor [HER] 1 or erbB-1)	Activating variant(s) in EGFR kinase (eg, S768I, L858R, L861Q, G719X, exon 19 deletions)	Variants in the *EGFR* gene are observed in about 15% of NSCLC in the United States. In Asian populations, the incidence of *EGFR* mutations is 22–62%.	EGFR tyrosine kinase inhibitors (gefitinib, erlotinib, afatinib, osimertinib, dacomitinib)	Advanced NSCLC that is positive for activating EGFR variant(s) is sensitive to EGFR-targeted TKIs. Analysis for the presence or absence of an activating variant (eg, exon 19 deletions or exon 21 substitution variants such as L858R) in EGFR is the standard approach to decide whether to use an EGFR TKI for the initial treatment of advanced NSCLC. Note that amplification of EGFR gene or EGFR overexpression by IHC does not predict improved outcomes with EGFR TKI.
HER2 gene	*HER2* gene amplification	*HER2* gene amplification is present in about 20% of breast cancers and 11–25% of gastric cancers.	Trastuzumab, pertuzumab, ado-trastuzumab emtansine, fam-trastuzumab deruxtecan-nxki, abemaciclib	HER2 is a receptor tyrosine protein kinase. It acts as an oncogene, mainly because amplification of the gene induces protein overexpression in the cellular membrane, leading to advantageous properties for malignant cells. Patients with *HER2* gene amplification are candidates for treatment with the *HER2*-directed antibody drug trastuzumab or pertuzumab. Patients without *HER2* amplification will not benefit from the treatment. FISH with labeled DNA probes to the pericentromeric region of chromosome 17 and to the HER2 locus is used to determine if a patient's breast cancer has *HER2* gene amplification. IHC stains are also used to determine if the tumor exhibits HER2 protein overexpression. Companion diagnostic test (Ki-67 IHC) should be performed before considering adjuvant abemaciclib plus endocrine therapy in HER-2 negative, hormone receptor-positive early breast cancer.
Isocitrate dehydrogenase-1/2 (*IDH1/2* gene)	*IDH1* pathogenic variants (R132 locus); *IDH2* pathogenic variants (R140 or R172 loci)	*IDH1/2* variants are detected in 15–20% of AML and 4–5% of chronic myeloid neoplasms (MDS, MPN).	Enasidenib, ivosidenib	*IDH1* or *IDH2* variants perturb DNA and histone methylation and lead to aberrant gene expression in hematopoietic stem cells through production of an abnormal metabolite, 2-hydroxyglutarate. The impact of *IDH1/2* variants in AML is age- and context-dependent. Enasidenib and ivosidenib are selective variant IDH2 and IDH1 inhibitors, respectively, and are indicated for the treatment of patients with relapsed or refractory and IDH-variant AML.
KRAS gene	*KRAS* pathogenic variants (in codons 12 and 13)	Present in 30–40% of CRC and 20–25% of NSCLC. *KRAS* G12C variant is present in 12–14% of lung adenocarcinomas.	For CRC: Cetuximab Penitumumab For NSCLC: Gefitinib Erlotinib Sotorasib	The *KRAS* gene, a human proto-oncogene, encodes one of the proteins in the EGFR signaling pathway critical in the development and progression of cancer, particularly CRC and NSCLC. Patients with cancer and variant *KRAS* are not likely to respond to drugs targeting the EGFR pathway. To avoid unnecessary toxicity and cost, all patients being considered for anti-EGFR therapy should undergo *KRAS* variant testing of their tumors. Sotorasib is approved for adult patients with *KRAS* G12C-variant advanced or metastatic NSCLC (second-line therapy).

(*continued*)

Table e5–2. Selected pharmacogenetic tests: clinical relevance[1] (listed in alphabetical order, within categories). (continued)

Pharmacogenetic Biomarker	Selected Variants (variant allele, activity)	Allele Frequency	Drugs	Clinical Relevance
Microsatellite instability-high (MSI-H) due to a deficiency in the mismatch repair (MMR) system because of variations in MMR-specific proteins, including MLH1, MSH2, MSH6, PMS2, or EPCAM	MSI-H (high rate of variation in microsatellite length exists across the genome) indicates underlying deficiency in DNA MMR capability, which in turn is caused by variations in one of the DNA MMR genes (*MLH1, MSH2, MSH6, PMS2, EPCAM*). MSI-H status is determined by PCR- or NGS-based tests, whereas MMR deficiency (MMR-D) is typically assessed by IHC.	Frequencies of MSI-H/MMR-D in advanced/metastatic cancers: 16% endometrial, 9% colorectal, 3% gastric, 5% esophageal, 21% neuroendocrine (GI tract), 16% small bowel, 3% squamous (skin), 3% basal cell (skin), 3% bladder, 2% prostate, 1–2% small cell lung, biliary, pancreatic, thyroid, or unknown primary.	Pembrolizumab, nivolumab	Pembrolizumab and nivolumab (immune checkpoint inhibitors) are approved for patients with unresectable or metastatic, MSI-H or MMR-D solid tumors that have progressed following prior treatment and who have no satisfactory alternative treatment options, or patients with MSI-H or MMR-D CRC that has progressed following treatment with a fluoropyrimidine, oxaliplatin, and irinotecan. The treatment confers a significant survival benefit.
Programmed death ligand 1 (PD-L1)	PD-L1 protein expression as determined by qualitative IHC	PD-L1 expression level is measured using the tumor proportion score, the percentage of tumor cells staining for PD-L1 (0–100%). Approximately one-third of NSCLC cases have detectable PD-L1 expression by IHC. PD-L1 is expressed in 65–100% cHL and about 50% of PMBCL.	Pembrolizumab, cemiplimab-rwlc, nivolumab	PD-L1 is an immune-related biomarker that can be expressed on tumor cells. PD-L1 testing determines which patients are likely to benefit from treatment with an immune checkpoint inhibitor that targets PD-L1. Overexpression of PD-L1 is an approved companion diagnostic test for pembrolizumab and other immune checkpoint inhibitors in NSCLC with no EGFR or ALK aberrations, gastric/gastroesophageal junction cancer, squamous cell esophageal cancer, cervical cancer, urothelial cancer, triple-negative breast cancer, cHL, and PMBCL.

[1] Testing of these genetic biomarkers prior to instituting drug therapy is recommended or required per US FDA-approved drug labels. The predictive biomarkers for hematological and oncological drugs are regulatorily approved under companion diagnostics, which is a rapidly evolving area.

↓, decreased; ↓↓, markedly decreased; none, no activity; ↑, increased; >, single wild-type to variant nucleotide switch at the specific gene location.

6-MP, 6-mercaptopurine; 6-MMP, 6-methylmercaptopurine; 6-TG, 6-thioguanine; AML, acute myeloid leukemia; AZA, azathioprine; CF, cystic fibrosis; cHL, classic Hodgkin lymphoma; CRC, colorectal cancer; FISH, fluorescence in-situ hybridization; GEJ, gastroesophageal junction; IHC, immunohistochemistry; MDS, myelodysplastic syndrome; MPN, myeloproliferative neoplasm; NADPH, nicotinamide adenine dinucleotide phosphate; NGS, next-generation sequencing; NSCLC, non–small cell lung cancer; PMBLC, primary mediastinal B-cell lymphoma; TKI, tyrosine kinase inhibitor.

Reference Intervals for Commonly Used Tests

Chuanyi Mark Lu

e5-03

Table e5–3. Reference intervals for commonly used tests (listed in alphabetical order).[1,2]

Conventional metric units × Conversion factor = SI units
SI units ÷ Conversion factor = Conventional metric units

Test	Specimen	Conventional Metric Units	Conversion Factor	SI Units[2]	Collection
Acetaminophen	Serum	10–20 mg/L **Panic:** > 50 mg/L	6.616	66–132 mcmol/L **Panic:** > 331 mcmol/L	SST, plain red
Acetoacetate	Serum or urine	Negative (< 5 mg/dL) Toxic level: > 100 mg/dL	0.098	Negative (< 0.49 mmol/L) Toxic level: > 9.8 mmol/L	SST or urine container
Activated clotting time (ACT)	Whole blood	70–180 seconds (method-specific)			Collect in a plastic syringe without anticoagulant
Adrenocorticotropic hormone (ACTH)	Plasma	9–52 pg/mL (laboratory-specific)	0.22	2–11 pmol/L	Siliconized glass or plastic (lavender)
Alanine aminotransferase (ALT, SGPT, GPT)	Serum or plasma	0–35 U/L (laboratory-specific)	0.017	0–0.6 mckat/L (laboratory-specific)	SST, plain red, PPT (light green)
Albumin	Serum or plasma	3.4–4.7 g/dL	10.00	34–47 g/L	SST, PPT (light green)
Albumin	Urine	< 30 mg/24 h; < 20 mcg/min (timed collection) Albumin/creatinine ratio: < 30 mg/g (spot urine)			Clean urine container
Aldosterone	Serum	**Salt-loaded** (120 mEq Na^+/d for 3–4 days): Supine: 3–10 ng/dL Upright: 5–30 ng/dL **Salt-depleted** (10 mEq Na^+/d for 3–4 days): Supine: 12–36 ng/dL Upright: 17–137 ng/dL	27.74	 83–277 pmol/L 139–831 pmol/L 332–997 pmol/L 471–3795 pmol/L	SST, plain red
	Urine	**Salt-loaded** (120 mEq Na^+/d for 3–4 days): 1.5–12.5 mcg/24 h **Salt-depleted** (10 mEq Na^+/d for 3–4 days): 18–85 mcg/24 h	2.77	4.2–34.6 nmol/d 49.9–235.5 nmol/d	Urine bottle containing boric acid (must be refrigerated during collection)

Conventional metric units × Conversion factor = SI units SI units ÷ Conversion factor = Conventional metric units					
Test	**Specimen**	**Conventional Metric Units**	**Conversion Factor**	**SI Units**[2]	**Collection**
γ-Glutamyl transpeptidase (GGT)	Serum or plasma	9–85 U/L (laboratory-specific)	0.017	0.15–1.42 mckat/L (laboratory-specific)	SST, PPT (light green)
Gastrin	Serum	< 100 pg/mL (laboratory-specific)	1.00	< 100 ng/L (laboratory-specific)	SST
Glomerular filtration rate, estimated (eGFR)	Serum or plasma	> 60 mL/min/1.73 m^2 (calculated based on creatinine and/or cystatin C level) Creatinine and/or cystatin C based eGFR calculation equation without the race variable is recommended			SST, PPT (light green)
Glucagon	Plasma	20–100 pg/mL	1.00	20–100 ng/L	Lavender
Glucose	Serum or plasma	60–110 mg/dL **Panic:** < 40 or > 400 mg/dL	0.0555	3.33–6.11 mmol/L **Panic:** < 2.22 or > 22.20 mmol/L	(Fasting) SST, PPT (light green), gray
Glucose-6-phosphate dehydrogenase (G6PD) screen	Whole blood	5–14 U/g Hb	0.02	0.1–0.28 mckat/L	Lavender
Glutamine	CSF	6–15 mg/dL **Panic:** > 40 mg/dL	68.42	411–1028 mcmol/L **Panic:** > 2737 mcmol/L	Collect CSF in a plastic tube
Glycated (glycosylated) hemoglobin (HbA_{1c})	Whole blood	3.9–5.6% (method-dependent)			Lavender, pink
Growth hormone (GH)	Serum or plasma	0–5 ng/mL	1.00	0–5 mcg/L	SST, PPT (light green)
Haptoglobin	Serum or plasma	46–316 mg/dL (acute phase reactant; also used in evaluation of hemolysis)	0.01	0.5–3.2 g/L	SST, PPT (light green)
Hematocrit (Hct)	Whole blood	Male: 39–49% Female: 35–45% (age-dependent)	0.01	Male: 0.39–0.49 Female: 0.35–0.45	Lavender, pink
Hemoglobin A_{1c} (See Glycated hemoglobin)	Whole blood	4.0–5.6% (method-dependent)	(A_{1c}% –2.15) × 10.93	20–38 mmol/mol	Lavender, pink
Hemoglobin A_2 (HbA_2)	Whole blood	1.5–3.5% of total hemoglobin	0.01	0.015–0.035	Lavender
Hemoglobin electrophoresis	Whole blood	HbA: > 95% HbA_2: 1.5–3.5% HbF: < 2% (age-dependent)			Lavender
Hemoglobin, total (Hb)	Whole blood	Male: 13.6–17.5 g/dL Female: 12.0–15.5 g/dL (age-dependent) **Panic:** ≤ 7 g/dL	10.00	Male: 136–175 g/L Female: 120–155 g/L (age-dependent) **Panic:** ≤ 70 g/L	Lavender

(*continued*)

Table e5–3. Reference intervals for commonly used tests (listed in alphabetical order).[1,2] (continued)

Conventional metric units × Conversion factor = SI units
SI units ÷ Conversion factor = Conventional metric units

Test	Specimen	Conventional Metric Units	Conversion Factor	SI Units[2]	Collection
Heparin anti-Xa assay, chromogenic	Plasma	Therapeutic ranges: UFH: 0.30–0.70 U/mL LMWH: 0.50–1.10 U/mL (twice-daily dose) or 1.1–2.0 U/mL (once-daily dose) Fondaparinux: 0.6–1.5 U/mL			Blue
Heparin-associated antibody (heparin-induced thrombocytopenia)	Serum	Negative			SST
High-density lipoprotein (HDL) cholesterol	Serum or plasma	Male: 27–67 mg/dL Female: 34–88 mg/dL (HDL cholesterol > 60 mg/dL is thought to lower risk of coronary heart disease)	0.0259	0.7–1.73 mmol/L 0.88–2.28 mmol/L	SST, PPT (light green) (fasting)
HIV RNA, quantitative (viral load)	Plasma	Negative (or < 40 copies/mL, assay-specific)			Lavender, PPT (light green)
HIV screening	Serum or plasma	EIA: Negative Antibody and p24 antigen combination assay: Negative			SST, PPT (light green), lavender
Homocysteine	Serum or plasma	4.5–12 mg/dL (method- and age-dependent)	7.397	33.29–88.76 mcmol/L	SST, PPT (light green)
5-Hydroxyindoleacetic acid (5-HIAA)	Urine	2–8 mg/24 h	5.23	10–40 mcmol/d	Urine bottle containing hydrochloric acid
IgG index	Serum and CSF	0.29–0.69 ratio (CSF:serum ratio)			SST or plain red (for serum) and glass or plastic tube (for CSF)
Immunoglobulins (Ig)	Serum	IgA: 78–367 mg/dL IgG: 583–1761 mg/dL IgM: 52–335 mg/dL	0.01	IgA: 0.78–3.67 g/L IgG: 5.83–17.6 g/L IgM: 0.52–3.35 g/L	SST
Insulin, immunoreactive	Serum or plasma	6–35 mcU/mL (laboratory-specific)	6.945	42–243 pmol/L	SST, PPT (light green)
Insulin-like growth factor-1	Serum	123–463 ng/mL (age- and sex-dependent)	1.0	123–463 mcg/L	SST, plain red
Iron (Fe)	Serum or plasma	50–175 mcg/dL	0.179	9–31 mcmol/L	SST, PPT (light green)
Iron-binding capacity, total (TIBC)	Serum or plasma	250–460 mcg/dL	0.179	45–82 mcmol/L	SST, PPT (light green)

(*continued*)

Table e5–3. Reference intervals for commonly used tests (listed in alphabetical order).[1,2] (continued)

Conventional metric units × Conversion factor = SI units SI units ÷ Conversion factor = Conventional metric units					
Test	**Specimen**	**Conventional Metric Units**	**Conversion Factor**	**SI Units[2]**	**Collection**
JAK2 pathogenic variants (mutations) (V617F or exon 12/13 variant), qualitative	Whole blood	Negative (Positive: myeloproliferative neoplasms, ie, polycythemia vera [95%], essential thrombocythemia [70%], and primary myelofibrosis [60%])			Lavender
Kappa and lambda free light chains, quantitative (serum free light chain [FLC] assay)	Serum	Free kappa: 0.57–2.63 mg/dL Free lambda: 0.33–1.94 mg/dL Free kappa/lambda ratio: 0.26–1.65	0.01	5.7–26.3 × 10^{-3} g/L 3.3–19.4 × 10^{-3} g/L	SST, plain red
Ketone bodies	Serum or plasma	Qualitative: Negative Quantitative: < 10 mg/dL	10.0	< 100 mg/L	SST, PPT (light green)
Lactate dehydrogenase (LD)	Serum or plasma	88–230 U/L (laboratory-specific)	0.02	1.46–3.82 mckat/L (laboratory-specific)	SST, PPT (light green)
Lactic acid (lactate)	Venous blood	0.5–2.0 mEq/L	1.00	0.5–2.0 mmol/L	Gray (iced)
Low-density lipoprotein (LDL) cholesterol (calculated or direct)	Serum or plasma	Desirable: < 130 mg/dL (< 99 mg/dL for patients with CHD) Borderline: 130–159 mg/dL High risk: ≥ 160 mg/dL	0.0259	< 3.37 mmol/L (< 2.57 mmol/L) 3.38–4.13 mmol/L > 4.16 mmol/L	SST, PPT (light green) (fasting)
Lead (Pb)	Whole blood	Child: < 25 mcg/dL Adult: < 40 mcg/dL	0.0483	Child: < 1.21 mcmol/L Adult: < 1.93 mcmol/L	Dark blue (trace metal free)
Leukocyte (WBC) count, total (WBC count)	Whole blood	4.8–10.8 × 10^9/L **Panic:** < 1.5 × 10^9/L	1.00	4.8–10.8 × 10^9/L **Panic:** < 1.5 × 10^9/L	Lavender
Lipase	Serum or plasma	0–160 U/L (laboratory-specific)	0.02	0–2.66 mckat/L (laboratory-specific)	SST, PPT (light green)
Luteinizing hormone (LH)	Serum or plasma	Female: Follicular phase 1–18 mU/mL Luteal phase 0.4–20 mU/mL Midcycle 24–105 mU/mL Postmenopausal 15–62 mU/mL Male: 1–10 mU/mL (laboratory-specific)	1.00	Female: 1–18 U/L 0.4–20 U/L 24–105 U/L 15–62 U/L Male: 1–10 U/L (laboratory-specific)	SST, PPT (light green)
Lymphocyte count, absolute	Whole blood	0.8–3.5 × 10^9/L	1.00	0.8–3.5 × 10^9/L	Lavender

(*continued*)

Table e5–3. Reference intervals for commonly used tests (listed in alphabetical order).[1,2] (continued)

Conventional metric units × Conversion factor = SI units SI units ÷ Conversion factor = Conventional metric units					
Test	**Specimen**	**Conventional Metric Units**	**Conversion Factor**	**SI Units[2]**	**Collection**
Magnesium (Mg^{2+})	Serum or plasma	1.8–3.0 mg/dL **Panic:** < 0.5 or > 4.5 mg/dL	0.411	0.75–1.25 mmol/L **Panic:** < 0.2 or > 1.85 mmol/L	SST, PPT (light green)
Mean corpuscular hemoglobin (MCH)	Whole blood	27–34 pg	1.00	27–34 pg	Lavender
Mean corpuscular hemoglobin concentration (MCHC)	Whole blood	31–36 g/dL	10.00	310–360 g/L	Lavender
Mean corpuscular volume (MCV)	Whole blood	80–100 fL	1.00	80–-100 fL	Lavender
Metanephrines, free	Plasma	Normetanephrine: < 0.9 nmol/L Metanephrine: < 0.5 nmol/L			Lavender
Metanephrines, fractionated	Urine (24-hour collection)	Metanephrine: 60–200 mcg/24 h Normetanephrine: 120–510 mcg/24 h (age-dependent)			Urine bottle containing boric acid or acetic acid
Methemoglobin (MetHb)	Whole blood	< 1.5% of total hemoglobin	0.01	< 0.015 fraction of total hemoglobin	Blood gas syringe, lavender or green for total Hb
Methylmalonic acid	Serum or plasma	0–47 mcg/L	8.475	0–0.4 mcmol/L	SST, PPT (light green)
Monocyte count, absolute	Whole blood	0.2–0.8 × 10^9/L	1.00	0.2–0.8 × 10^9/L	Lavender
Neutrophil count, absolute (ANC)	Whole blood	2.0–8.6 × 10^9/L **Panic:** < 0.5 × 10^9/L	1.00	2.0–8.6 × 10^9/L **Panic:** < 0.5 × 10^9/L	Lavender
Osmolality	Serum or plasma	275–293 mOsm/kg H_2O **Panic:** < 240 or > 320 mOsm/kg H_2O	1.00	275–293 mmol/kg H_2O **Panic:** < 240 or > 320 mmol/kg H_2O	SST, PPT (light green)
	Urine	Random: 100–900 mOsm/kg H_2O	1.00	Random: 100–900 mmol/kg H_2O	Urine container
Osteocalcin	Serum or plasma	Child or adolescent (age 7–17 years): 25–300 ng/mL Adult: 10–15 ng/mL	1.00	Child or adolescent (age 7–17 years): 25–300 mcg/L Adult: 10–15 mcg/L	SST, red, lavender, PPT (light green)
Oxygen, partial pressure (Po_2)	Whole blood	83–108 mm Hg **Panic:** < 50 mm Hg (arterial)	0.13	11.04–14.36 kPa **Panic:** < 6.5 kPa (arterial)	Heparinized syringe (iced)
Pancreatic elastase, fecal	Formed stool	> 200 mcg/g			Leak-proof container (freeze immediately)

(continued)

Table e5–3. Reference intervals for commonly used tests (listed in alphabetical order).[1,2] (continued)

Conventional metric units × Conversion factor = SI units SI units ÷ Conversion factor = Conventional metric units					
Test	**Specimen**	**Conventional Metric Units**	**Conversion Factor**	**SI Units[2]**	**Collection**
Pancreatic polypeptide	Serum or plasma	< 430 pg/mL (age-dependent and laboratory-specific)			SST, red or lavender (fasting sample, iced)
Parathyroid hormone (PTH), intact	Serum or plasma	Intact PTH: 11–54 pg/mL (laboratory-specific)	0.11	Intact PTH: 1.2–5.7 pmol/L (laboratory-specific)	Red, SST, PPT (light green)
Partial thromboplastin time, activated (PTT)	Plasma	25–35 seconds (reference interval varies) **Panic:** ≥ 60 seconds, or >100 seconds for unfractionated heparin monitoring			Blue
pH	Whole blood	Arterial: 7.35–7.45 Venous: 7.31–7.41 **Panic:** ≤ 7.25 or ≥ 7.60			Heparinized syringe (iced)
Phosphorus	Serum or plasma	2.5–4.5 mg/dL **Panic:** < 1.0 mg/dL	0.323	0.8–1.45 mmol/L **Panic:** < 0.32 mmol/L	SST, PPT (light green)
Plasminogen	Plasma	70–113% (activity)	1.00	70–113%	Blue
Platelet count (Plt)	Whole blood	150–450 × 10^9/L **Panic:** < 25 × 10^9/L	1.0	150–450 × 10^9/L **Panic:** < 25 × 10^9/L	Lavender
Platelet function test (PFA-100 closure time) (CEPI: collagen/epinephrine cartridge; CADP: collagen/ADP cartridge)	Whole blood	CEPI: 70–170 seconds (laboratory-specific) CADP: 50–110 seconds (laboratory-specific)	1.0	CEPI: 70–170 seconds (laboratory-specific) CADP: 50–110 seconds (laboratory-specific)	Blue
Platelet-associated IgG	Plasma or serum	Negative			Lavender, PPT, SST
Porphobilinogen (PBG)	Urine	Negative (ie, < 8.8 mmol/L or < 11 mmol/24 h)			Protect from light
Potassium (K^+)	Serum or plasma	3.5–5.0 mEq/L **Panic:** < 3.0 or > 6.0 mEq/L	1.00	3.5–5.0 mmol/L **Panic:** < 3.0 or > 6.0 mmol/L	SST, PPT (light green)
Procalcitonin (PCT)	Serum or plasma	< 0.10 ng/mL (< 0.25 ng/mL in chronic kidney failure)	1.00	< 0.10 mcg/L (< 0.25 mcg/L in chronic kidney failure)	SST, PPT (light green)
Procollagen type 1 intact N-terminal propeptide (PINP)	Serum	20–100 ng/mL (age- and sex-dependent)	1.00	20–100 mcg/L (age- and sex-dependent)	SST, plain red
Prolactin (PRL)	Serum or plasma	< 20 ng/mL	1.00	< 20 mcg/L	SST, PPT (light green)
Prostate-specific antigen (PSA)	Serum or plasma	0–4 ng/mL	1.00	0–4 mcg/L	SST, red, PPT (light green)

(*continued*)

Table e5–3. Reference intervals for commonly used tests (listed in alphabetical order).[1,2] (continued)

Conventional metric units × Conversion factor = SI units SI units ÷ Conversion factor = Conventional metric units					
Test	**Specimen**	**Conventional Metric Units**	**Conversion Factor**	**SI Units**[2]	**Collection**
Protein C	Plasma	70–170% (functional) 60–150% (antigenic)			Blue
Protein electrophoresis	Serum	Adult:	10.00		SST, red
		Albumin: 3.3–4.7 g/dL		33–47 g/L	
		α_1: 0.1–0.4 g/dL		1–4 g/L	
		α_2: 0.3–0.9 g/dL		3–9 g/L	
		β: 0.7–1.5 g/dL		7–15 g/L	
		γ: 0.5–1.4 g/dL (polyclonal)		5–14 g/L (polyclonal)	
Protein S (antigen)	Plasma	55–155%			Blue
Protein, total	Serum or plasma	6.0–8.0 g/dL	10.00	60–80 g/L	SST, PPT (light green)
Prothrombin time (PT)	Plasma	11–15 seconds **Panic:** ≥ 30 seconds (laboratory-specific)			Blue
Red blood cell count (RBC)	Whole blood	Male: 4.3–6.1 × 10^{12}/L	1.00	4.3–6.1 × 10^{12}/L	Lavender
		Female: 3.5–5.5 × 10^{12}/L		3.5–5.5 × 10^{12}/L	
Renin activity	Plasma	**High-sodium diet** (75–150 mEq Na$^+$/d): Supine: 0.2–2.3 ng/mL/h Standing: 0.6–3.0 ng/mL/h **Low-sodium diet** (30–75 mEq Na$^+$/day): Standing: 3.0–15.0 ng/mL/h			Lavender
Reticulocyte count	Whole blood	25–125 × 10^9/L	1.00	25–125 × 10^9/L	Lavender
Rheumatoid factor (RF)	Serum	Negative (ie, < 1:16)			SST, red
Russell viper venom clotting time (dilute) (RVVT)	Plasma	24–37 seconds			Blue
Salicylate (aspirin)	Serum	200–300 mg/L	0.00724	1.45–2.17 mmol/L	Plain red
		Panic: > 350 mg/L		**Panic:** > 2.53 mmol/L	
SARS-CoV-2 (RT-PCR or antigen)	Swab-VTM or saliva	Negative (Positive: symptomatic or asymptomatic COVID-19 acute infection)			Tube with VTM
SARS-CoV-2 antibody (anti-nucleocapsid IgM and/or IgG; anti-spike IgM and/or IgG)	Serum or plasma	Negative (Positive: acute and convalescent COVID-19 infection; status post–COVID-19 vaccination; antibody profile is vaccine-specific)			SST, PPT (light green)

(*continued*)

Table e5–3. Reference intervals for commonly used tests (listed in alphabetical order).[1,2] (continued)

Conventional metric units × Conversion factor = SI units
SI units ÷ Conversion factor = Conventional metric units

Test	Specimen	Conventional Metric Units	Conversion Factor	SI Units[2]	Collection
Sodium (Na$^+$)	Serum or plasma	135–145 mEq/L **Panic:** < 125 or > 155 mEq/L	1.00	135–145 mmol/L **Panic:** < 125 or > 155 mmol/L	SST, PPT (light green)
Somatostatin	Plasma	< 25 pg/mL (laboratory-specific)	0.611	< 15.28 pmol/L (laboratory-specific)	Lavender, PPT (white)
ST2, soluble (sST2)	Serum	Male: < 52 ng/mL; Female: < 38 ng/mL (laboratory-specific)			Plain red, SST
Testosterone	Serum or plasma	Male: 175–781 ng/dL Female: 10–75 ng/dL	0.0347	Male: 6–27 nmol/L Female: 0.3–2.6 nmol/L	SST, PPT (light green)
Thyroglobulin	Serum or plasma	3–42 ng/mL	1.00	3–42 mcg/L	SST, PPT (light green)
Thyroid-stimulating hormone (TSH)	Serum or plasma	0.35–3.0 mcU/mL **Panic:** > 50 mcU/mL	1.00	0.35–3.0 mU/L **Panic:** > 50 mU/L	SST, PPT (light green)
Thyroid-stimulating immunoglobulin (TSI), Thyroid-stimulating hormone receptor antibody (TSH-R Ab [stim])	Serum	Negative (ie, < 130% of basal activity; based on cAMP generation in thyroid cell tissue culture			SST, red
Thyroxine, free (FT$_4$)	Serum or plasma	0.7–1.86 ng/dL	12.87	9–24 pmol/L (varies with method)	SST, PPT (light green)
Thyroxine (T$_4$), total	Serum or plasma	5–11 mcg/dL	12.87	64–142 nmol/L	SST, PPT (light green)
Transferrin	Serum or plasma	190–375 mg/dL	0.01	1.9–3.75 g/L	SST, PPT (light green)
Transferrin, carbohydrate-deficient (CDT)	Serum	< 1.3% method-dependent			SST, red
Transferrin receptor, soluble (sTfR)	Serum or plasma	2.2–5 mg/L 1.9–4.4 mg/L (laboratory-specific)			SST, PPT (light green)
Triglycerides	Serum or plasma	< 165 mg/dL	0.0113	< 1.8 mmol/L	SST, PPT (light green) (fasting)
Triiodothyronine (T$_3$), total	Serum or plasma	95–190 ng/dL	0.0154	1.5–2.9 nmol/L	Red, SST, PPT (light green)
Troponin-I (cTnI)	Plasma or serum	< 0.05 ng/mL (method-dependent)	1.0	< 0.05 mcg/L (method-dependent)	PPT (light green), SST, red
Troponin-I, high-sensitivity (hs-cTnI)	Plasma or serum	< 0.027 ng/mL (laboratory-specific)	1000	< 27 ng/L (laboratory-specific)	PPT (light green)
Uric acid	Serum or plasma	Male: 2.4–7.4 mg/dL Female: 1.4–5.8 mg/dL	59.48	Male: 140–440 mcmol/L Female: 80–350 mcmol/L	SST, PPT (light green)

(*continued*)

Table e5–3. Reference intervals for commonly used tests (listed in alphabetical order).[1,2] (continued)

Conventional metric units × Conversion factor = SI units SI units ÷ Conversion factor = Conventional metric units					
Test	**Specimen**	**Conventional Metric Units**	**Conversion Factor**	**SI Units[2]**	**Collection**
Vanillylmandelic acid (VMA)	Urine	2–7 mg/24 h (< 15 mg/g creatinine, random urine)	5.05	10–35 mcmol/d	Urine bottle containing acetic or hydrochloric acid
Vitamin B_{12}	Serum or plasma	170–820 pg/mL	0.738	125–600 pmol/L	SST, PPT (light green)
Vitamin D, 1,25-dihydroxy ($1,25[OH]_2D$)	Serum or plasma	20–76 pg/mL	2.6	48–182 pmol/L	SST, PPT (light green)
Vitamin D, 25-hydroxy (25[OH]D)	Serum or plasma	20–50 ng/mL	2.496	50–125 nmol/L	SST, PPT (light green)
von Willebrand factor (vWF)	Plasma	50–180% (activity and antigen) (acute phase reactant)			Blue
White blood cell count	Whole blood	$4.8–10.8 \times 10^9$/L **Panic:** $< 1.5 \times 10^9$/L	1.00	$4.8–10.8 \times 10^9$/L **Panic:** $< 1.5 \times 10^9$/L	Lavender

[1] The reference intervals given here in conventional metric units and in SI units (international system of units) are from several large medical centers. Always use the reference intervals provided by your clinical laboratory, since intervals may be method-dependent.

CSF, cerebrospinal fluid; EIA, enzyme immunoassay; hCG, human chorionic gonadotropin; LMWH, low-molecular-weight heparin; PPT, plasma preparation tube; RT-PCR, real time-polymerase chain reaction; SST, serum separator tube; UFH, unfractionated heparin; VTM, viral transport medium. See Table e5–3 for commonly used blood specimen collection tubes.

e5-04

Commonly Used Blood Specimen Collection Tubes

Chuanyi Mark Lu

Table e5–4. Commonly used blood specimen collection tubes (listed in alphabetical order).

Tube	Tube Contents	Typical Use
Blue	Sodium citrate	Coagulation studies
Black	Sodium citrate None (plain, sterile black screw top)	ESR (with sodium citrate) Body fluids for microbiology (plain, sterile black screw top)
Dark navy blue	Clot activator (trace metal free)	Trace metals (eg, lead, mercury, arsenic)
Gold SST	Clot activator and gel for serum separation	Serum chemistry tests
Gray	Inhibitor of glycolysis (sodium fluoride)	Lactic acid; glucose
Green	Lithium heparin (dark green, without gel; light green PPT, with gel for plasma separation); Sodium heparin (green top, without gel)	Plasma chemistry tests (light green PPT); point-of-care chemistry tests, troponin or cyanosis panel (dark green); chromosome analysis, FISH, or flow cytometry (green top)
Lavender or Pink	K_2EDTA	CBC (whole blood); blood banking (plasma); molecular testing (cell-based); flow cytometry (immunophenotyping)
Orange RST	Thrombin and gel for serum separation	Serum chemistry tests
Plain red	None	Blood banking (serum); therapeutic drug monitoring
Streck Cell-free DNA BCT	K_3EDTA plus a cell preservative in a liquid medium	Whole blood for cell-free DNA (cfDNA) based molecular tests
White PPT	K_2EDTA and gel for plasma separation	Molecular testing (plasma-based)
Yellow	ACD (acid citrate dextrose) SPS (sodium polyanethol sulfonate)	ACD: HLA typing; blood banking (plasma); flow cytometry (immunophenotyping) SPS: Blood culture (microbiology)

ACD, acid citrate dextrose; EDTA, ethylenediamine tetra-acetic acid; FISH, fluorescence in-situ hybridization; HLA, human leukocyte antigen; PPT, plasma preparation tube; RST, rapid serum tube; SPS, sodium polyanethol sulfonate; SST, serum separator tube.
